CHAPTER 19

Pharmacologic Basis for High-dose Chemotherapy

Borje S. Andersson, Benigno C. Valdez and Roy B. Jones
The University of Texas M.D. Anderson Cancer Center, Houston, TX, USA

Introduction

High-dose chemotherapy utilized to "condition" patients prior to a transplant was based on the idea of eradicating the tumor and "creating space," then engraftment would occur. This was accomplished by applying an empiric combination of total body irradiation (TBI) and cyclophosphamide [1]. Later, combination chemotherapy without TBI gained popularity [2]. The most commonly used regimen in allogeneic stem-cell transplantation (allo-SCT) was for many years the (oral) busulfan–cyclophosphamide combination introduced by Santos et al. [3,4], and subsequently revised by Tutschka et al. [5]. Cyclophosphamide (CY) was used mostly for its immunosuppressive properties. However, agents such as melphalan (MEL) used by itself in multiple myeloma, and in various combinations, have also been successfully employed. A listing of the most commonly used cytotoxic agents currently used in (high-dose) conditioning chemotherapy preceding allo- and auto-SCT is presented in Table 19.1.

The concept of "creating space" has gradually been replaced by a more nuanced view of the mechanisms involved in engraftment of allogeneic cells and a complex picture is gradually emerging. Similarly, the idea of eradicating tumor cells with high-dose chemotherapy while simply replacing the patient's immune system has been substituted by a model where engraftment along with tumor killing is facilitated by the conditioning regimen. Once engrafted, the new immune system will provide an immunologic graft-versus-tumor effect against residual tumor cells to accomplish long-term freedom from progression. Conditioning regimens were previously designed by using cytotoxic agents in empiric combinations near their maximum doses in single-agent therapy. More recently, data from preclinical studies of combinations of drugs which optimize synergistic antitumor interactions while minimizing the risk for normal tissue damage are increasingly used to guide the design of new conditioning programs. Such novel regimes allow us to improve both the antileukemic effects and the immunosuppressive capability of the preparative regimen. Incorporation of pharmacogenetic information about metabolic drug handling permits the use of agents that target different metabolic pathways, thereby increasing patient safety. Much developmental work in the last decade has contributed to introducing innovative combinations of nucleoside analogs or other DNA damage-modifying agents with external-beam radiotherapy (XRT) and/or alkylating agents [6–10]. These regimens appear safer and possibly more efficacious than the older empiric programs. Further, treatment intensity can be modulated in proportion to the effectiveness of immune-mediated tumor killing by the graft. These approaches aim at optimizing patient safety and minimizing serious treatment-related adverse events while maximizing antitumor effects.

The more recent introduction of nucleoside analog (NA) combinations in pretransplant conditioning provides both the intense immunosuppression necessary to facilitate engraftment and an improved antitumor effect by inducing DNA damage and inhibiting DNA repair. Further, the different metabolic pathways for DNA-alkylating agents and NAs contribute to retaining or improving patient safety; each drug can be used at virtually full dose compared with its use as a single agent. Thus, the high incidence of overwhelming toxicity which directed the development of reduced-intensity conditioning is now being challenged with a graded approach that includes "myeloablative, reduced-toxicity" therapy. This methodology has been facilitated by an increasing level of mechanistic understanding of interactions between different cytotoxic agents. It is also clear that studies of genetic variability in the enzyme systems involved in the metabolic pathways that determine both activation and deactivation of the cytotoxic agents will assist in designing more efficacious and less toxic regimens. In this chapter, we review the cytotoxic agents that are most commonly used in pretransplant conditioning and some of the emerging molecular, pharmacokinetic, pharmacodynamic, and pharmacogenetic data that are of importance for the development of even more effective high-dose therapy. These data will not, however, suffice to optimize the drug administration in individual patients, where we look forward to an increasing role for therapeutic dose monitoring based on pharmacokinetics. We also examine some data for clinical dose-limiting toxicities and their pharmacologic basis. We limited our review to regimens commonly used in the period 2009–2011.

Pharmacology of drugs used in high-dose chemotherapy

Alkylating agents

Busulfan

Busulfan (BU) belongs to the general class of bifunctional methanesulfonic acid esters that have varying length of the interspacing methylene groups. There are several members of this class that have cytotoxic activity; busulfan (1,4-butanediol dimethylsulfonate,

Figure 19.1) is the clinically most used. Its cytotoxic action is generally believed to be through alkylating guanine residues in DNA-forming adducts [11]. These adducts can be monoadducts, or DNA intra- and inter-strand cross-links and also DNA–protein cross-links. BU is chemically unstable in an aqueous environment and does not need cellular activation. The most important detoxification step is glutathione *S*-transferase (GST) A-mediated BU conjugation with glutathione (GSH) to form a tetrahydrothiophenium ion (Figure 19.2) [12,13]. The GSTA1 isoenzyme [14] constitutes about 65-80% of hepatic GST activity [15]. Depletion of GSH increases the target tissue sensitivity to BU. Experimental overexpression of GSTA1 induces relative resistance, but cellular BU resistance is multifactorial, and GSH depletion in resistant tumor cells may not restore sensitivity to this drug [16]. In the clinical setting, it is uncertain how much a varied cellular concentration of GSTA1 or any of the other GST isoenzymes contributes to BU resistance, since systematic studies are needed to confirm the clinical relevance of the intriguing experimental data.

Table 19.1 Conditioning regimen drugs given to HSCT recipients registered with the CIBMTR between 2009 and 2011[a]

Allogeneic ($n = 26538$)			Autologous ($n = 27005$)		
Drug	***N***	**%**	**Drug**	***N***	**%**

[a] Excludes drugs used for less than 1% of patients.

Data kindly provided by the Center for International Blood and Marrow Transplant Research, (CIBMTR) (2012).

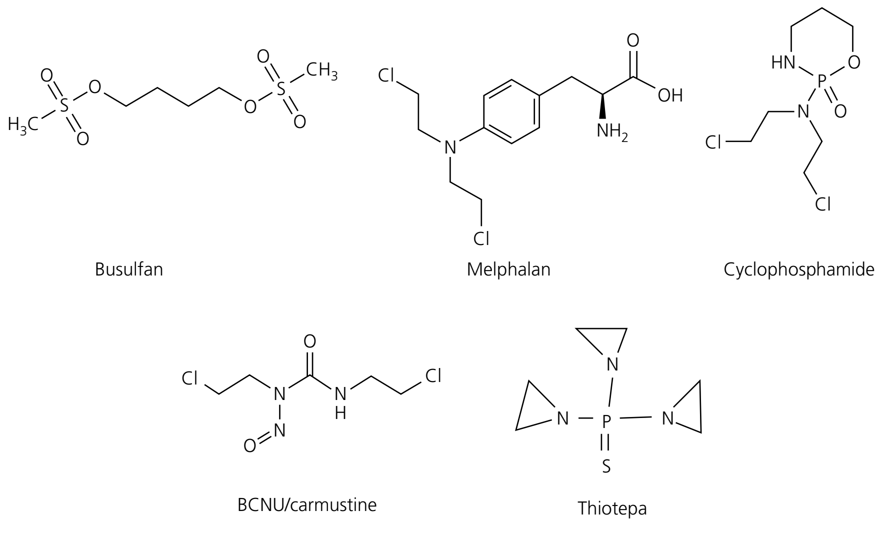
Metabolism and mechanism of action

BU is very lipophilic and is thought to diffuse freely into the target cells/tissues [17]. Although BU does not seem to be a substrate for any of the hepatic cytochrome P450 isoenzymes, its GSH-conjugated sulfonium ion is a substrate for hepatic P450 metabolism. Its further metabolism is partly determined by tissue alkylation and partly by hepatic and urinary excretion through the formation of sulfolane, 3-hydroxysulfolane, and tetrahydrothiophene 1-oxide (Figure 19.2). These metabolites constitute approximately 70% of a given dose and are excreted in urine within the first 72 hours. Only about 1–2% of a given dose is excreted unchanged in urine, and a similar amount of intact drug is excreted through the bile [12].

The relative importance of the various GST isoenzymes in BU metabolism and clearance and their importance for clinical adverse events after high-dose therapy and treatment outcome have been studied by several groups; both GSTA1 and GST-M have been correlated with altered drug clearance and cellular drug resistance [14,18]. The combined effects of genotypic isoenzyme variants have been implicated in altered drug clearance to a magnitude that may influence treatment outcome. In addition, there is still somewhat limited knowledge about intracellular BU disposition beyond GSH conjugation. Finally, BU efflux from cells has been inadequately studied. BU systemic exposure is a (good) surrogate marker for anticipated drug/regimen-related toxicity, but many clinical reports include patients conditioned with (oral) BU–CY, and both the CY component and its timing and sequencing relative to BU contribute to the risk for hepatotoxicity [19–21]. The effects of prior chemotherapy and concomitant medications given shortly before and during the preparative regimen have also been inadequately studied [22]. The metabolism and systemic clearance of BU, and of most other alkylating agents, are complex and at best incompletely understood [23].

Pharmacokinetics

BU is available both as a tablet and as a parenteral solution. Oral drug bioavailability is highly variable, ranging from less than 10% to virtually 100%; on average it is approximately 70–80% [24,25]. BU pharmacokinetics are linear and follow first-order kinetics in a wide dosing interval, ranging from the conventional 2–6 mg once daily up to 3–4 mg/kg given once daily (or about 130–160 mg/m^2) in



Busulfan

Melphalan

Cyclophosphamide

BCNU/carmustine

Thiotepa

conditioning therapy. Plasma protein binding is less than 10%, and the half-life is about 2.5–3.5 hours (range approximately 1.5–6 hours). The average adjusted clearance is about 110–115 mL/min/m^2 (range approximately 50-150 mL/min/m^2) [26]. The clearance is age dependent; children in the first 6 months of life have poorly developed hepatic function and a relatively decreased clearance, whereas at 1–4 years they have a higher clearance than adults. Second, in the age interval 1–4 years, children have a relatively increased GST activity in the intestinal tract, which may influence the initial handling of oral drug, which likely affects the bioavailability and first-pass drug elimination. These findings have led to suggestions of drug dosing that takes into account both age and body weight rather than weight/body surface area alone [27]. Parenteral BU demonstrated an improved safety profile in high-dose therapy, and in pediatric practice the formulation contributed to improved outcome when both weight and age are considered in the dosing algorithm. Alternatively, since BU does not need activation, it is a good candidate for therapeutic drug monitoring (TDM) that takes individual variability in metabolic drug handling into account. BU pharmacokinetics (PKs) are reproducible over multiple doses in an individual patient, but the area under the curve (AUC) can vary up to 2-3-fold between patients, suggesting that TDM of the parenteral product may have benefit [28].

The transition to parenteral BU applied with PK-guided TDM in high-dose therapy yields consistent dose delivery/systemic exposure, and recent clinical transplant data support the use of intravenous (IV) BU as safer and therefore preferable to oral BU in high-dose therapy. However, even though BU exhibits linear first-order kinetics, its utility and PK characteristics are influenced by numerous factors, as discussed previously. Further, BU PKs to some extent depend on the patient's underlying disease; thalassemia patients on average exhibit increased drug clearance, possibly related to increased hepatic GSTA1 activity. Finally, concomitant administration of other drugs, both chemotherapeutic agents and supportive care medications, may alter BU clearance.

Dose-limiting toxicities

Myelotoxicity is the most notable side effect of BU. This made it an almost ideal agent for pretransplant conditioning therapy. Additionally, nausea/vomiting are pronounced with oral BU since the drug is locally irritating to the gastric mucosa. When used in high-dose therapy, mucositis is common, and grand mal seizures have been reported with an incidence of 5–10% [29,30]; this mandates the use of prophylactic antiseizure medication. Phenytoin is commonly utilized, but owing to concern about an interaction between phenytoin and BU some investigators favor benzodiazepines, which do not affect BU clearance [31]. A hallmark adverse effect of high-dose BU is hepatic veno-occlusive disease (VOD), also termed sinusoidal obstruction syndrome (SOS), which may lead to multiorgan failure that commonly has a lethal outcome. The incidence increases in proportion to higher BU exposures and the risk also increases when BU is administered with other alkylating agents (e.g. CY/MEL/thioTEPA), which consume hepatic GSH. The end result can be serious/overwhelming hepatic injury if the dose and schedule of all the agents are not carefully considered. A commonly occurring adverse effect of high-dose BU is a reversible, cosmetic skin discoloration that becomes noticeable after a few weeks and which is more pronounced in individuals of a darker complexion.

Drug interactions

Other medications administered close to BU may alter the metabolic transformation of BU, GSH conjugation and outward cellular transport of (GSH-conjugated) drug, much of which is only partially known. The administration of a variety of agents in close proximity to BU may dramatically alter drug clearance; however, the mechanism(s) involved beyond those shown in Figure 19.3 are incompletely understood. Drugs that are known to, or probably, interact with BU metabolism include agents such as CY, thioTEPA, MEL, phenytoin, metronidazole, itraconazole, deferasirox, and ethacrynic acid. Caution is recommended if patients receive tyrosine kinase inhibitors, and also the mammalian target of

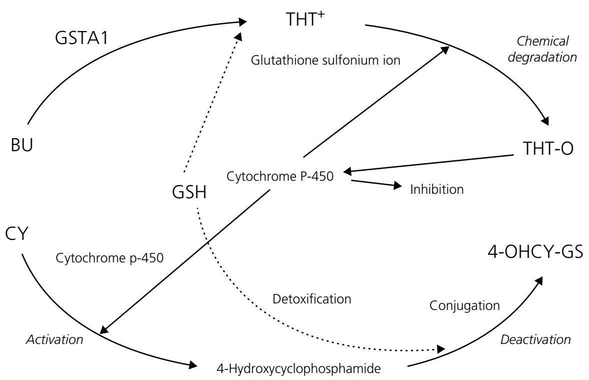

Figure 19.3 Interaction between busulfan and cyclophosphamide. Source: Hassan and Andersson 2013 [13]. Reproduced with permission of Future Medicine Ltd.

rapamycin (mTOR) inhibitors sirolimus and everolimus (observations from the M.D. Anderson Cancer Center, 2010–2013, and the Clinical Trials Network, 2011, respectively) (Figure 19.3). The end result can be excessive toxicity [19,20]. Novel regimens/combinations should be used only after careful phase I and II testing.

These findings highlight the possibility that both cytotoxic and non-cytotoxic drugs may alter BU clearance if they are used in close proximity with the conditioning therapy. Such interaction(s) may also affect both cellular resistance and corollary sensitivity to BU and other cytotoxic agents used in the treatment regimen. Even with an increased understanding of individual patients' GST and P450 isoenzyme patterns, it is recommended to use PK-based TDM whenever possible to optimize systemic BU exposure. It must be remembered that not all drug interactions are negative; this is exemplified by the synergistic cell kill that can be accomplished by an in-depth analysis of the molecular mechanisms of drug action(s) and interaction(s) together with studies of sequencing of the various agents [10,32–34].

Melphalan

Melphalan (L-phenylalanine mustard, MEL) belongs to the nitrogen mustard class of alkylating agents (for molecular structure, see Figure 19.1). These were initially explored during World War II while evaluating chemical warfare agents. During the following decade, its antitumor activity was appreciated. Finally, in 1992, the drug was formulated for IV use, making the investigation of high-dose MEL with stem-cell transplantation (SCT) feasible.

MEL was originally synthesized in 1953 [35]. The prototype bis-2-chloroethylamine mustard functionality was linked to L-phenylalanine. In water, each arm of the chloroethylamine group can form a positively-charged aziridinium ring. This unstable reactive intermediate can combine with various tissue nucleophiles (negatively charged species) to form an alkylation product. When the alkylated species is a DNA base, the second chloroethyl group can undergo the analogous reaction with the complementary DNA strand to form a "DNA cross-link." While much evidence supports DNA alkylation as the dominant antitumor mechanism, this chemistry is broadly applicable to a wide variety of tissue nucleophiles and the importance of these alkylation products to toxic and therapeutic effects is only partly understood.

MEL undergoes hydrolysis in water, and the chlorine atoms are replaced by hydroxyl groups. The resulting mono- and dihydroxy-MEL compounds are more stable, form aziridinium rings poorly, and have virtually no antitumor activity. The rate of this reaction is determined by the chloride concentration in a saline solution. In physiologic saline, MEL is completely hydrolyzed and inactivated over 8 hours [36]. In dextrose–water solutions, hydrolysis proceeds so rapidly that the latter must never be used to formulate the drug for clinical use. Further, because of hydrolysis, MEL in saline solution must be infused within 60 minutes of dilution. MEL is poorly water soluble, so its stock diluent is comprised of ethanol and propylene glycol.

Metabolism and disposition

MEL has no known metabolites, and its hydrolysis products are inactive. MEL primarily binds to plasma proteins (mostly albumin), with one-third of the binding being covalent/irreversible [36]. Radiolabeled-drug studies demonstrate that at most 15% of total drug label is excreted renally over 24 hours following dosing [36]. Known MEL hydrolysis confirms that most of the label represents inactive hydroxylated derivatives. These data strongly suggest that neither renal excretion nor metabolism play important roles in MEL disposition.

Toxicity

The dominant toxicity of MEL in conventional doses is hematologic and gastrointestinal (GI) (nausea/vomiting). Used in transplantation, GI and mucosal toxicities with frequent diarrhea dominate. High-dose MEL can cause sporadic, usually reversible, but occasionally lethal, cardiac toxicity. Renal tubular injury causing mild, asymptomatic proteinuria is common. Within 5–7 days of dosing, significant myelo- and profound immunosuppression occur.

Pharmacokinetics

Most PK studies do not differentiate between bound and unbound MEL. Taking this into account, the available data suggest that the plasma half-life ($T_{1/2}$) of free MEL is between 30 and 60 minutes and the volume of distribution is throughout total body water [37]. Representative drug clearance is 500–600 mL/min. There is at least a fourfold inter-individual variability in systemic exposure and PK parameters. The explanation for this variation is unknown. Taken together, the data suggest that tissue alkylation is the primary route of elimination of drug from the plasma. TDM of MEL is investigational. The use of oral cooling with ice slurry over 2 hours after high-dose MEL has been shown to be effective in reducing oral mucositis. This strategy is based on the short MEL half-life [38].

Cellular pharmacology

MEL enters the cell primarily by energy-dependent active transport [39]. The high-affinity L-amino acid transporter mediates most of the uptake. High extracellular concentrations of leucine or other amino acids can competitively inhibit MEL uptake.

Once inside the cell, the low chloride–high phosphate concentrations accelerate both hydrolysis and formation of reactive intermediates. In this environment, GSH conjugation becomes an important detoxification mechanism [40]. Little is known about specific mechanisms of MEL migration to the nucleus, but DNA is believed to be the primary target for therapeutic effects. Initial mono-alkylated products are primarily formed at the N^7-position of guanine or the N^3-position of adenine [41]. Whereas the rate of formation of mono-adducts is rapid, di-adduct formation (cross-links resulting from the bifunctionality of MEL) occurs over 6-18 hours. Cross-links can be either inter- or intra-strand, but most evidence suggests that inter-strand cross-links are primarily responsible for pharmacodynamic effects, and that the duration of the cross-links is predictive of these effects. In this light, the cellular effectiveness of cross-link repair is a major determinant of antitumor activity and probably also for normal-organ toxicity [42].

Drug–drug interactions/pharmacogenetics

Because of the importance of GSH conjugation for MEL detoxification, both intracellular GSH concentration and GST activity play important roles in MEL activity and toxicity. Any drug that forms GSH conjugates might deplete GSH and increase cellular MEL sensitivity. MEL produces important oral and GI mucosal toxicity in transplant doses, so in combination alkylating agent regimens the optimal dose may be lower than the 200 mg/m^2 dose commonly used for single-agent treatment. GSTA1 and GSTP1 predominate in GI mucosa, with GSTA1 dominating in the stomach and small intestine and GSTP1 dominating in the colon [43].

If high-dose MEL is combined with other agents that are nephrotoxic, caution is advised; single-agent MEL is generally not considered to be nephrotoxic, but when combined with certain nucleoside analogs, such as 2-chlorodeoxyadenosine (M.D. Anderson Cancer Center, 1996, unpublished work), or more recently with clofarabine, a significant fraction of the patients developed renal failure [44].

Drug resistance

Cellular uptake, GSH/GST activity, and DNA repair alterations are associated with tumor MEL resistance. Lowered expression of CD98, as representing the MEL carrier, has been found in MEL-resistant myeloma cells [45]. Changes in cellular GSH content have also been associated with MEL resistance [46]. GSTP1 often predominates in tumors and catalyzes the conjugation of MEL to GSH. Greater GSTP1 activity in tumors can reflect MEL resistance [47]. Finally, when compared with untreated patients who had no inter-strand cross-link repair activity, patients with myeloma having previous MEL treatment could repair 40–100% of established cross-links. This suggests augmented repair activity as a possible resistance mechanism.

Cyclophosphamide

Cyclophosphamide [(*R*,*S*)-*N*,*N*-bis(2-chloroethyl)-1,3,2-oxazaphosphinan-2-amine 2-oxide) is a nitrogen mustard (Figure 19.1) that alkylates DNA. It is a prodrug that is converted to active forms with cytotoxic activity. Cyclophosphamide (CY) was approved by the US Food and Drug Administration (FDA) in 1959 as an antitumor agent.

Metabolism and mechanism of action

CY is a prodrug that is converted by hepatic cytochrome P450 (CYP) mixed-function oxidases to both active and inactive metabolites. *N*-Dechloroethylation of CY is mediated mostly by CYP3A4/3A5 [48], and yields the non-toxic 2-dechloroethylcyclophosphamide, and also chloroacetaldehyde, which is both neuro- and nephrotoxic. Oxidation at the C4-position is mediated by several CYP isoforms [49]. This oxidation step gives rise to 4-hydroxycyclophosphamide (4-OHCY), which tautomerizes to aldophosphamide; 4-OHCY may also be enzymatically converted to inactive 4-ketocyclophosphamide. Aldophosphamide may be oxidized to inactive carboxyphosphamide by aldehyde dehydrogenases (ALDH1A1 and ALDH3A1) [50] or non-enzymatically converted to phosphoramide mustard and acrolein, both of which are active metabolites. Phosphoramide mustard is a DNA alkylator that forms inter- and intra-strand cross-links between the N^7-positions of guanine similar to those of other DNA alkylating agents. Phosphoramide mustard is thought to be the primary cytotoxic metabolite. Acrolein is also cytotoxic and is considered responsible for causing hemorrhagic cystitis. This is counteracted by adding 2-mercaptoethanesulfonate (MESNA) to the treatment with high doses of CY.

The cytotoxic activity of CY and its immunomodulatory potential make it a good component of the pre-transplant regimens for hematopoietic stem-cell transplantation (HSCT). Although effective as a single agent, it is usually combined with other cytotoxic drugs or TBI. In conventional chemotherapy, R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine and prednisone) has a cure rate of 30–40% for aggressive non-Hodgkin lymphoma [51], but high-dose chemotherapy with CY prior to HSCT is a most effective treatment for relapsed, refractory non-Hodgkin lymphoma. High-dose CY in combination with TBI or BU with or without etoposide is considered effective conditioning therapy preceding allo-HSCT [52].

High-dose CY *after* HSCT was recently introduced as prophylaxis for graft-versus-host disease (GVHD). It is commonly administered together with tacrolimus/cyclosporine and mycophenolate mofetil. Hematopoietic stem cells possess high levels of aldehyde dehydrogensase and therefore are resistant to CY killing. Delayed T-cell engraftment and preferential killing of proliferating alloreactive, as opposed to regulatory, T-cell compartments appear to reduce GVHD activity [53]. This approach may allow the use of mismatched allotransplants with greater safety, and is being explored.

Pharmacokinetics

CY is always given intravenously in transplant doses. It has an elimination half-life ($T_{1/2}$) that ranges between 3 and 12 hours. Approximately 5–25% of the dose is excreted intact in the urine. Its elimination is dose dependent, with significant excretion of parent drug at daily doses greater than 1.5 g/m^2, and in pediatric patients where several investigators have reported up to 40% excretion of intact CY.

Adverse effects

CY, like its close relative ifosfamide, produces nausea, vomiting, alopecia, and gonadal failure. Other adverse effects include nephrotoxicity, neurotoxicity, infertility, hemorrhagic cystitis, myelo- and immunosuppression, and a potential for leukemogenesis. Hepatic injury is most commonly seen when CY is given with other (DNA-alkylating) agents, or together with TBI. High-dose CY may, through acrolein, lead to inhibition of hepatic GST activity. Acrolein has also been implicated in directly depleting hepatic GSH stores [54]. High-dose CY has been associated with (sub-)acute cardiac toxicity, cardiac ("pump") failure and arrhythmias, typically occurring at any time from about 24 hours to 2 weeks after the completion of CY administration. GSH has been demonstrated to play an important role in protection against cardiac toxicity. Acrolein-induced GSH depletion may therefore explain CY-associated cardiotoxicity [55]. The heart toxicity is dose dependent and doses above 7 g/m^2 should be avoided because of a rapidly increasing risk for cardiac complications [56].

Drug interactions

CY produces glutathione depletion and thus may potentiate other alkylating agents detoxified by this mechanism (for example, see Figure 19.3 and the Busulfan section of this chapter).

BCNU/carmustine

BCNU [1,3-bis(2-chloroethyl)-1-nitrosourea; carmustine] is an alkylating agent used to treat several types of cancer (Figure 19.1). It has been used since 1971 to treat Hodgkin lymphoma, multiple myeloma, and brain tumors. BCNU has been popular in the treatment of brain tumors owing to its high lipophilicity and capacity to cross the blood–brain barrier. It is commonly used as part of conditioning therapy for auto-HSCT; almost 31% of high-dose auto-HSCT performed in the United States between 2009 and 2011 used BCNU in the regimen (Table 19.1). It was approved by the FDA in 1977 for the treatment of brain tumors, Hodgkin disease and other lymphomas, and multiple myeloma. Its derivative, lomustine or CCNU [1-(2-chloroethyl)-3-cyclohexyl-*N*-nitrosourea], was approved by the FDA in 1976 for the treatment of brain tumors and Hodgkin disease.

Metabolism and mechanism of action

The mechanism of action of BCNU has not been fully elucidated, but alkylation of DNA and RNA is believed to be responsible for its cytotoxicity. The drug decomposes to chloroethyl moieties which alkylate reactive sites on nucleic acids and proteins. BCNU is a monofunctional nitrosourea, but it can produce DNA cross-links. One strand is chloroethylated and displacement of the chloride ion on the other strand results in an ethyl bridge that prevents unwinding of the DNA [57]. The active form of BCNU reacts with the O^6-position of guanine producing *O*^{6}-ethylguanine, triggering mismatch repair, and induces apoptosis and senescence [58]. Apoptosis and senescence are preceded by heterochromatin organization partly contributed by decreased histone 3-acetylation and increased histone 3-trimethylation on Lys9 [59]. BCNU can also cause carbamoylation of protein lysine residues after formation of an isocyanate, but this might be a minor contributory mechanism to its cytotoxicity. BCNU kills cells in all stages of the cell cycle.

O^6-Ethylguanine is repaired by *O*^{6}-alkylguanine–DNA alkyltransferase (AT), and elevated AT levels have been linked to BCNU resistance [60]. Altered base and nucleotide excision repair may also contribute to such resistance; enhanced cytotoxicity of BCNU was observed in cell lines deficient in excision repair enzymes [61]. Chronic lymphoid leukemia (CLL) patients resistant to nitrogen mustard treatment have elevated level of DNA excision repair enzymes [62]. No correlation has been observed between the rate of repair of *O*^{6}-ethylguanine and the levels of GSH, GST activity, or P-glycoprotein expression in primary cells from CLL patients [63].

BCNU is commonly combined with etoposide, Ara-C (cytarabine), and melphalan (MEL) ("BEAM"), an effective high-dose salvage regimen used with auto-HSCT for refractory Hodgkin lymphoma and diffuse large B-cell lymphoma (DLBCL) [64].

Pharmacokinetics

BCNU is not stable in aqueous solution. Intravenous administration results in a highly variable half-life ranging from about 15 to 90 minutes. No parent product is excreted and approximately 30–80% of the degradation products are excreted in the urine within 24 hours. Its alkylating metabolites rapidly enter the cerebrospinal fluid.

Adverse effects

The major side effect of BCNU is myelosuppression, and at high doses it may cause hepatic VOD/SOS, pulmonary fibrosis, renal failure, and secondary leukemia. Other risks include infection due to myelo- and immunosuppression, thrombocytopenia, nausea and vomiting, skin flushing, redness of face, dizziness and loss of balance, and hypotension.

Drug interactions

Some of the drugs that interact with BCNU include cimetidine, digoxin, leflunomide, natalizumab, phenytoin, fosphenytoin, pimecrolimus, roflumilast, tacrolimus and trastuzumab.

ThioTEPA

ThioTEPA (TT) was synthesized in the early 1950s in the search for novel antitumor alkylating agents. The *N*-triethylenephosphoramide backbone (TEPA or T; see Figure 19.1 for structure) contains three aziridinyl three-membered rings that can hydrolyze to produce alkylating moieties similar to those of nitrogen mustard(s). TEPA was active but chemically unstable, so the more stable sulfur analog *N*-triethylenethiophosphoramide (TT) was synthesized and entered clinical use. Its dominant hematologic toxicity made it an attractive agent to explore in solid tumors and it was soon formulated for IV use. These properties made it an attractive compound for HSCT.

Chemistry

TT was synthesized to place three aziridine rings immediately adjacent to a strongly electron-withdrawing thiophosphorus functional group. In this way, electron-rich N- and O-functional groups combine with the already unstable and partially positively charged aziridine ring to form an alkylation product. This type of reaction is particularly favored when the tissue pH is lower, such as in tumors [65]. Because TT has three aziridine rings, it is capable of forming cross-links in DNA or between DNA and other cellular macromolecules. TT is converted to its oxo derivative T both as a result of hydrolysis and through CYP mediation. Both TT and T have antitumor activity, the relative amount of which varies between experimental systems.

Metabolism and toxicity

As shown in Figure 19.4, TT can be oxidized to T via CYP P450. Both T and TT are GSH-conjugated through GST. Both TT and T are active but the relative organ-specific toxicity has been incompletely studied, and it is hazardous to draw clinical conclusions based upon existing metabolic data. CYP2B6 and CYP3A4/5 are predominantly responsible for the TT conversion to T (Figure 19.4). There are at least four polymorphic alleles of CYP2B6 comprising up to 60% of a typical US population, but at most these could account for a 10–30% variation in aggregate TT and T exposure. CYP3A4 polymorphisms account for only 6% of the population and could account for 10% variability in TT plus T exposure. GSTA polymorphisms have no important effect, but GSTP, which often predominates in tumors, might result in 40–50% increased net tumor exposure in polymorphic homozygous patients with decreased conjugating capacity [66].

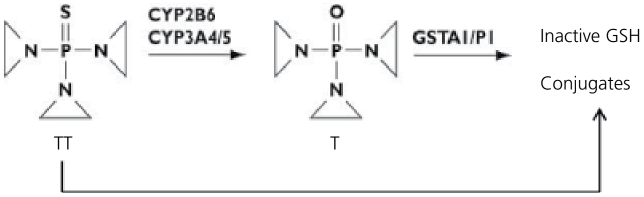

Figure 19.4 Conversion of thioTEPA (TT) to its oxo derivative TEPA (T) and their conjugation with glutathione (GSH).

TT has a broad spectrum of non-hematologic toxicity, including hepatic toxicity and oral and GI mucositis, and also central nervous system (CNS) and cutaneous toxicity [67]. CNS toxicity manifested by cortical dysfunction was dose limiting in a single-agent high-dose SCT study. TT can enhance the toxicity of (an-)other simultaneously administered alkylating agent(s) through depletion of GSH, so that (reactive intermediates of) the other agent(s) cannot be effectively detoxified.

Pharmacokinetics

There are no definitive reports of the PKs of protein-bound versus -unbound TT and T. A representative plasma half-life of total TT is 3 hours and that of T is 2–3 times longer. In most patients, the systemic exposure of T is therefore 3-4 times greater than that of TT [64]. Clearance of TT is 200–300 mL/min/m^2 and inter-patient variability is reported as 4–7-fold. Therefore, it is not surprising that sporadically serious toxicity is seen with doses above 1000 mg/m^2 (25 mg/kg). Lower doses are usually employed in high-dose combination chemotherapy. Renal excretion accounts for 10% or less of intact T and TT.

Cellular pharmacology

Cellular uptake is through passive diffusion. Once inside the cell, the drug rapidly binds to various macromolecules, and GSH conjugation accounts for a major part of the detoxification. Different tissues, organs, and tumors have differing GST subtypes, and the activity or polymorphism of these various isoenzymes can influence organ- or tissue-specific drug effects.

The movement of TT from the cytoplasm to the nucleus has not been studied. Once proximate to DNA, TT or T can form both single-stranded adducts and DNA double-stranded cross-links through the activity of the aziridine rings. Through hydrolysis, it is also possible that a single aziridine ring can form a single-stranded adduct through attack by an electron-rich DNA component [68]. Inter-strand cross-links, however, are generally considered as a major cytotoxic mechanism for all bifunctional (or, in the case of TT, trifunctional) alkylating agents. DNA adducts of TT primarily involve alkylation at the N^7-position of guanine or at the N^3- or N^7-positions of adenine [65].

Drug interactions

Because TT can react with a wide variety of tissue macromolecules containing nucleophilic sites, the administration of TT prior to a second cancer drug can produce changes in enzyme-mediated activation or metabolism of the second agent. Additionally, TT conjugation with GSH can reduce the GSH available to detoxify a second alkylating agent administered in close proximity to TT. If TT is administered prior to CY, the metabolic activation of CY by P450 is reduced [69]. This highlights the importance of paying attention to such interactions when designing new drug regimens. A "rest" day between administration of high-dose TT and other alkylating agents is often employed to allow normal tissue recovery from GSH depletion and oxidative stress. Through non-specific tissue alkylation, TT can reduce the activity of a variety of phase I and II metabolic pathways producing otherwise unanticipated changes in bioactivation or metabolism of concomitantly administered drugs.

Drug resistance

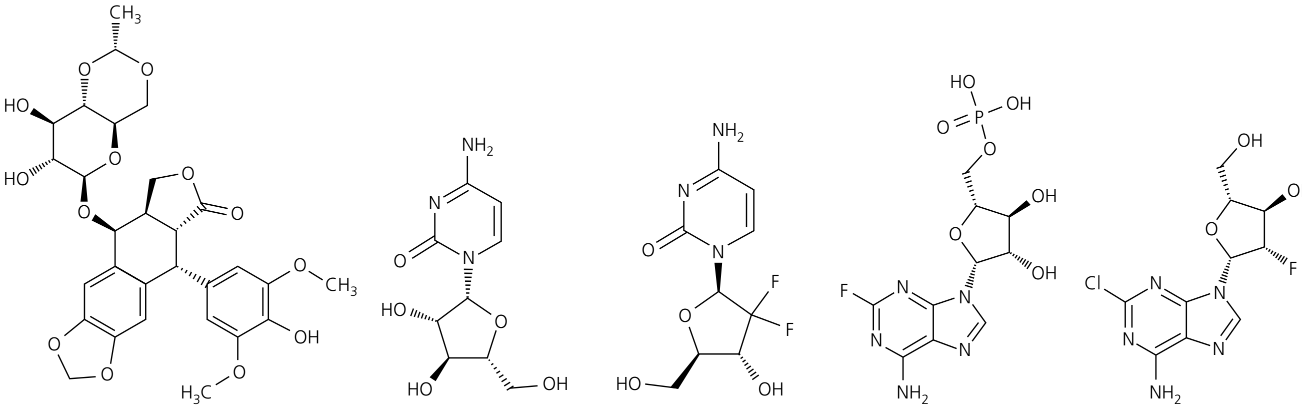
TT resistance in tumors can develop through GSTP polymorphisms. Resistance based upon alterations in GSH concentration or metabolism has been incompletely studied.

Topoisomerase inhibitors

Topoisomerases are enzymes that resolve the tension resulting from supercoiling, knotting, and catenation of DNA during replication and transcription. These enzymes bind to DNA, cut its phosphate backbone, allow the DNA to unwind, and then re-seal the break. Type I topoisomerases relax DNA tension by cutting one strand of a DNA double helix, letting it rotate around the uncut strand, and then re-ligating the cut. Type II topoisomerases cut both strands of a double helix, pass the unbroken DNA helix through it, and religate the broken strands. Topoisomerase II inhibitors stabilize the complex formed between topoisomerase II and the 5′-cleaved ends of the DNA and result in accumulation of DNA breaks that ultimately lead to DNA-damage response and trigger apoptosis. Two such agents, which are used as part of conditioning therapy, are etoposide and teniposide. One drawback of the DNA-damaging effects of topoisomerase inhibitors is the possible acquisition of secondary neoplasms.

Etoposide

Etoposide{4′-demethylepipodophyllotoxin9-[4,6-*O*-(*R*)-ethylidene]-β-D-glucopyranoside, VP-16} (Figure 19.5) or its derivative, etoposide phosphate, is a semisynthetic derivative of podophyllotoxin, a natural product from the May apple plant. It was approved by the FDA in 1983 for the treatment of testicular cancer and subsequently for the treatment of small-cell lung carcinoma in combination with other (approved) chemotherapeutic drugs.



Etoposide Cytarabine Gemcitabine Fludarabine Clofarabine

Figure 19.5 Structures of a topoisomerase inhibitor and nucleoside analogs used in HSCT.

Metabolism and mechanism of action

Etoposide is a complex molecule with a polar surface and a basic pK_a of 9.8 [70]. These properties prevent the drug from passing freely through the cell membrane. The mechanism of cellular uptake is not well defined but the human organic cationic transporter OCTN2, a high-affinity carnitine carrier, might be involved in its transport [71].

Etoposide is an active drug; its target is in the nucleus. It binds to and stabilizes the topoisomerase II-cleaved DNA complex (the cleavage complex), which is an intermediate in the removal of genomic knots and tangles by topoisomerase II. Etoposide prevents re-ligation of broken DNA strands catalyzed by the enzyme [72]. This results in accumulation of DNA breaks, which subsequently activate DNA-damage response and apoptosis. Etoposide specifically affects cells in the S and G2 phases of cell division.

The drug is primarily inactivated in the liver by 3′-demethylation mediated mainly by the cytochrome P450 system (specifically CYP3A4). Other metabolites identified in plasma and urine include *cis*-(picro)lactone, hydroxy acid derivatives, 4′-*O*-glucuronide of etoposide or agrycon, sulfate conjugates, and 3′-demethyletoposide [73].

There are two major mechanisms of resistance to etoposide: (1) increased expression of *MDR1*-encoded P-glycoprotein, multidrug resistance protein (MRP), and lung resistance protein (LRP), all of which mediate cellular efflux of etoposide [74], and (2) low expression, post-translational modifications and mutations of topoisomerase II [75]. Polymorphisms may play a critical role in the sensitivity of patients to etoposide. A genome-wide analysis of human cell lines identified 63 genetic variants that may contribute to etoposide-induced cytotoxicity [76].

Pharmacokinetics

An open two-compartment PK model of etoposide in leukemic children showed α-phase, β-phase, volume of distribution, and clearance of 1.2 h, 5.8 h, 3.1 L/m^2, and 19.5 mL/min/m^2, respectively [77]. The major metabolites were the *trans*- and *cis*-hydroxy acid derivatives in serum and urine [77]. In children with solid tumors, patients with pre-existing liver injury had a lower systemic etoposide clearance.

More recent studies showed a narrow therapeutic window and highly variable PKs of etoposide. Creatinine clearance correlates with etoposide clearance, but creatinine clearance alone is a poor predictor of etoposide systemic exposure; rather, free etoposide AUC is a better determinant of its pharmacodynamic effects [78].

Etoposide clearance and volume of distribution increase with increasing body weight in children undergoing auto-HSCT for solid tumors. Conversely, body mass index (BMI) does not seem to affect the outcome or toxicity of etoposide in acute lymphoblastic leukemia (ALL) patients [79].

Adverse effects

The more common and severe side effects of etoposide include myelosuppression, alopecia, constipation/diarrhea, secondary malignancies, cardiotoxicity, loss of consciousness, and fatigue.

Drug interactions

PK studies showed that cyclosporine treatment increased etoposide exposure by decreasing its clearance by as much as 71% [80]. Drugs that inhibit P450 CYP 3A4 (e.g., telithromycin and voriconazole) may reduce the metabolism of etoposide and increase its plasma concentration/systemic exposure.

Nucleoside analogs

Nucleoside analogs (NAs) are prodrugs which are very similar in structure to normal nucleosides (Figure 19.5). Structural modifications generally improve their aqueous solubility, stability and efficacy. The efficacy of NAs in the treatment of hematologic malignancies is partly due to the dependence of hematopoietic cells on nucleoside salvage synthesis [81]. Cells easily take them up, metabolize and incorporate them into DNA or RNA (Figure 19.6). In general, NAs are taken up by cells through nucleoside transporters. Once in the cytoplasm, they are phosphorylated to their triphosphate derivatives, considered to be the active forms that enter the nucleus and compete with normal nucleotide triphosphates in the synthesis of DNA and RNA. Their cytotoxicity is primarily attributed to inhibition of DNA synthesis and repair, which triggers DNA-damage response. Interference with DNA damage/repair in mitochondria may also mediate apoptotic cell death.

In the last decade, NAs have been increasingly used in high-dose therapy. They are typically combined with DNA alkylating agents for synergistic antileukemic effects during pre-transplant conditioning therapy. The synergistic cytotoxicity of these two classes of drugs can be primarily attributed to activation of DNA-damage response and apoptosis (reviewed in [82]) (Figure 19.7). Briefly, the initial incorporation of NAs into DNA strands inhibits DNA synthesis and repair, and also triggers histone modifications. Modified histones cause chromatin remodeling that yields better accessibility of genomic DNA to subsequent administration of DNA alkylators, resulting in propagation of DNA damage and consequent apoptosis [34]. Based on this model, chromatin modifiers are expected to improve further the efficacy of NAs and DNA alkylators. Addition of suberoylanilide hydroxamic acid (SAHA) to this combination, in fact, enhances their synergistic cytotoxicity [34,83]. Ongoing clinical trials of these drug combinations will be needed to elucidate whether the addition of agents such as histone deacetylase inhibitors and/or demethylating agents to a basic NA-alkylating agent “platform” combination will further enhance the conditioning regimen efficacy yet without jeopardizing patient safety.

Cytarabine

Cytarabine (1-β-ᴅ-arabinosylcytosine, or Ara-C) was the first analog of deoxycytidine to be synthesized and used in antitumor therapy (Figure 19.5). It is generally indicated for the treatment of acute myeloid leukemia (AML) and the blastic phase of chronic myelogenous leukemia (CML).

Metabolism and mechanism of action

Cytarabine enters the cells via the nucleoside transporter hENT1. It is phosphorylated by deoxycytidine kinase (DCK) to Ara-CMP and by nucleotide kinases to Ara-CTP. Its cytotoxicity is due to prevention of cytidylate to 2′-deoxycytidylate conversion [84], erratic coding when incorporated into DNA and RNA [85], and inhibition of DNA polymerase-α, DNA-strand elongation, and DNA repair. The prodrug is easily inactivated by cytidine deaminase (CDA) in the liver by deamination to Ara-U, which is excreted in the urine. Ara-CMP is dephosphorylated by 5′-nucleotidase NT5C2. Replacement of the 2′-OH group with fluorine yielded 2′-deoxy-2′-fluorocytidine (F-Ara-C), which exhibited 10-fold higher cytotoxicity than Ara-C in vitro, but a disappointingly low antitumor activity in vivo.

Apoptosis

Figure 19.6 Transport, activation, and mechanisms of action of nucleoside analogs (NAs). The prodrugs are taken up by cancer cell through nucleoside transporter and activated in the cytoplasm to their triphosphate form (NA-TP) by a series of kinases. The diphosphates (NA-DPs) inhibit ribonucleotide reductase and NA-TPs inhibit DNA synthesis and repair and RNA synthesis. The inhibition of DNA synthesis and repair causes DNA breaks and activation of DNA-damage response, which results in mitochondrial-dependent and -independent apoptosis. The decrease in mitochondrial transmembrane potential caused by NA-TPs and damaged DNA releases pro-apoptotic factors to the cytoplasm. Inhibition of ribonucleotide reductase decreases the physiological dNTP pools and increases the incorporation of NA-TPs into DNA and RNA, resulting in self-potentiation.

Chromatin remodeling
Alkylating agent(s)

Figure 19.7 Suggested mechanism of the synergistic cytotoxicity of gemcitabine (GEM) with other NAs [e.g., clofarabine (CLO)] and DNA alkylating agents (e.g., BU and MEL). The activated nucleoside analogs inhibit DNA synthesis and repair, which results in DNA damage. DNA breaks may cause histone modifications and chromatin remodeling, which may expose genomic DNA and make it more accessible to DNA alkylation. Attempts to repair DNA cross-links result in more DNA breaks and the cycle is further amplified by additional DNA alkylations. The amplified DNA damage results in cell death or apoptosis.

Pharmacokinetics

Approximately 13% of cytarabine binds to plasma proteins. Cytarabine is easily deaminated, resulting in a half-life of 10 minutes. As with several NAs, this rapid deamination becomes clinically relevant when bolus doses exceed the capacity of kinase activation, and forms the rationale for using prolonged cytarabine infusions.

Adverse effects

Cytarabine may cause leukopenia, thrombocytopenia, anemia, GI disturbances, stomatitis, conjunctivitis, interstitial pneumonitis, fever, dermatitis, palmar–plantar erythrodysesthesia ("hand–foot-syndrome"), nausea, hair loss, muscle or joint pain, and fatigue. At high doses, cytarabine may cause CNS toxicity, and also a "pulmonary leakage" syndrome that is responsive to preemptive steroid therapy.

Drug interactions

Cytarabine decreases the effect of digoxin.

Gemcitabine

In the search of more stable analogs of deoxycytidine, both H atoms at the 2′-position of Ara-C were replaced with fluorine, resulting in 2′,2′-difluorodeoxycytidine (gemcitabine, GEM; Figure 19.5). The product is considerably more resistant to deamination, and effectively impairs the growth of both solid and liquid tumors.

Metabolism and mechanism of action

GEM is hydrophilic and needs a transporter to pass through the cell membrane. It is taken up through equilibrative and concentrative nucleoside transporters hENT1, hENT2, hCNT1, or hCNT3. It is phosphorylated in the cytoplasm by DCK to dFdCMP, and this is considered to be the rate-limiting step in its activation. To a more limited extent, GEM can also be phosphorylated to dFdCMP by thymidine kinase in the mitochondria [86]. The second phosphorylation step in the cytoplasm is catalyzed by pyrimidine nucleoside monophosphate kinase (UMP/CMP kinase) to produce dFdCDP and subsequently phosphorylated by nucleotide diphosphate kinase (NDK) to dFdCTP.

GEM is recognized by several DNA polymerases as a natural substrate; it is incorporated into nascent DNA strands during synthesis, but prevents further DNA chain elongation after addition of one more deoxynucleotide [87]. This inhibition of DNA synthesis and DNA repair leads to increased DNA double-strand breaks and activation of DNA-damage response and apoptosis. GEM also inhibits RNA synthesis in a concentration- and time-dependent manner [88].

The diphosphorylated derivative dFdCDP binds to and inhibits ribonucleotide reductase (RNR), an enzyme that catalyzes the conversion of ribonucleotides into their deoxyribonucleotide forms. Inhibition of RNR decreases the NTP pools used for normal DNA synthesis, which causes enhanced GEM incorporation in the growing DNA strand. Such inhibition of RNR decreases the cellular concentration of dCTP, a feedback inhibitor of DCK, and results in the activation of the kinase, increased phosphorylation of dFdC, and greater self-potentiation of GEM.

Inactivation of GEM occurs primarily through deamination, which is catalyzed by deoxycytidine deaminase (dFdC to dFdU) and dCMP-deaminase or 5′-nucleotidase (dFdCMP to dFdUMP) [89]. dFdU is eliminated from the cell but its cellular re-entry competes with dFdC through the equilibrative nucleoside transporters, and it also modulates the phosphorylation of dFdC via DCK [90].

Pharmacokinetics

The volume of distribution (V_d) and half-life of GEM are influenced by the duration of the IV infusion. For short infusions (<70 min), V_d is 50 L/m^2 and $T_{½}$ is about 40-95 min; for prolonged infusions, V_d is up to 370 L/m^2 and $T_{½}$ is about 245–6408 min. Age and gender also affect the clearance of GEM, with women and the elderly exhibiting lower values. Both GEM and its metabolite dFdU are excreted in the urine.

Some genetic factors that affect the pharmacokinetics and pharmacodynamics of GEM have been identified. Since CDA detoxifies GEM, its activity correlates with GEM systemic exposure. Two single nucleotide polymorphisms (SNPs) in the *CDA* gene 79A>C (K27Q) (**2*) and 208G>A (A70T) (**3*) seem to correlate with a decreased enzymatic activity of CDA and cytotoxicity of GEM [91,92]. The C-allele in the 79A>C genotype is more frequent in Whites than Africans and Asians, whereas the 208G>A genotype has not been detected in Whites and African-Americans and at lower frequency in East Asian populations and some in Africans [93]. Other SNPs found associated with GEM PKs that have been found underscore the importance of studying larger patient populations.

Adverse effects

Myelosuppression is the principal dose-limiting toxicity of GEM when used as a single agent. Mild to moderate nausea, vomiting, and mild proteinuria and hematuria are commonly experienced. Fever, rash, dyspnea, edema, flu-like symptoms, infection, and alopecia occur in 10–40% of patients. More serious extrahematologic side effects, including myocardial infarction, cerebrovascular accidents, cardiac arrhythmias, and hypertension, have been experienced in ~2% of patients.

Drug interactions

GEM may increase the anticoagulant effects of warfarin analogs and enhance bleomycin toxicity. Paclitaxel increases GEM toxicity. owing to the profound effects of GEM on the various enzyme systems involved in its metabolism and on nucleoside metabolism in general, there is a significant potential for synergistic interactions with several other groups of cytotoxic agents, including, but not limited to, NAs, DNA-alkylating agents, and ionizing radiation, but so far only limited work has been carried out to exploit this systematically in a clinical setting. In particular, the inhibition of DNA repair by GEM and the activity of this drug in lymphomas make it an attractive drug for use in combination with alkylating-agents in salvage regimens for refractory Hodgkin and non-Hodgkin lymphomas [94].

Fludarabine

Fludarabine (FLU) is a monophosphorylated form of 9-β-D-arabinosyl-2-fluoroadenine (F-Ara-A), an analog of deoxyadenosine (Figure 19.5). F-Ara-A is more resistant to deactivation by adenosine deaminase compared with Ara-A and adenosine. FLU is approved by the FDA for the treatment of patients with B-cell chronic lymphocytic leukemia who are unresponsive to, or whose disease has progressed during treatment with, at least one standard DNA-alkylating agent. The wide use of FLU in non-myeloablative and in myeloablative, reduced-toxicity, conditioning therapy for allo-HSCT is attributed to both its immunosuppressive and its antitumor activities.

Metabolism and mechanism of action

FLU is negatively charged at physiological pH because of its functional phosphate group, and it cannot cross the cell membrane. Once given IV, it is converted by 5′-nucleotidases to its dephosphorylated form, which enters the cells mostly through nucleoside transporter hENT1 [95]. The prodrug is then phosphorylated by DCK to F-Ara-AMP and further phosphorylation by purine nucleotide kinase converts it to its active form F-Ara-ATP, which is incorporated into growing DNA strands and inhibits DNA synthesis. Since F-Ara-ATP inhibits DNA ligase I, an enzyme essential for joining DNA ends, both DNA replication and DNA repair are inhibited [96].

Pharmacokinetics

The limited PK data for FLU focus on its metabolite F-Ara-A. It follows linear PKs with extensive tissue distribution. FLU is primarily eliminated through the kidneys.

FLU cytotoxicity is associated with the cellular concentration of F-Ara-ATP, assayed in circulating myelo- and lymphoblasts. Infusions of 30 mg/m^2 FLU over 30 minutes result in 20–60 μM F-Ara-ATP in leukemia cells, which peaks after 4 hours [97]. The cellular concentration of F-Ara-ATP depends linearly on its plasma concentration and duration of infusion. Its cellular elimination is monophasic, with a median half-life of approximately 15 hours. When used in conditioning therapy, significant plasma concentrations have been reported for more than 48 hours after therapeutic infusions.

Adverse effects

Some serious side effects of FLU include immuno- and myelosuppression, infection, fever and chills, nausea, and vomiting. Other common adverse effects include malaise, fatigue, anorexia, weakness, and peripheral neuropathy. Doses in excess of 125 mg/m^2 daily for 4–7 days may result in lethal neurotoxicity, which can present as a Guillain–Barré-like syndrome [98].

Drug interactions

Severe toxicity may occur if FLU is combined with pentostatin, an inhibitor of adenosine deaminase. Dipyridamole may decrease the efficacy of FLU.

Clofarabine

The problems with the efficacy and stability of the first-generation purine NAs triggered the development of clofarabine (2-chloro-2′-arabinofluoro-2′-deoxyadenosine, C-Ara-FdA; CLO) (Figure 19.5). The incorporation of chlorine in the adenine ring makes it resistant to deamination and substitution with a fluorine atom in the ribose moiety makes the glycosidic bond resistant to phosphorolysis. It is approved by the FDA for the treatment of pediatric ALL in patients failing at least two prior regimens.

Metabolism and mechanism of action

CLO enters the cells through the human equilibrative nucleoside transporters (hENT1 and hENT2) and human concentrative nucleoside transporters (hCNT2 and hCNT3). It is phosphorylated by DCK in the cytoplasm and by deoxyguanosine kinase (DGK) in the mitochondria [99]. The phosphorylation of C-Ara-FdAMP to its diphosphate form by purine nucleotide monophosphate kinase determines its activation rate. It is further phosphorylated to its triphosphate form.

CLO cytotoxicity is related to its inhibition of DNA synthesis, inhibition of ribonucleotide reductase, and direct induction of apoptosis. At a ratio of C-Ara-FdATP to dATP one of >1, DNA strand elongation is significantly inhibited and causes DNA chain termination and DNA strand breaks. At lower ratios, CLO is incorporated into internal phosphodiester linkages and inhibits DNA repair. CLO can inhibit DNA synthesis by 75-95% when infused in humans at 22.5-55 mg/m^2 [100].

The diphosphate derivative of CLO inhibits RNR. This decreases the deoxynucleotide pool, enhances the incorporation of C-Ara-FdATP into DNA, and potentiates its ability to inhibit DNA synthesis. Inhibition of DNA synthesis triggers DNA-damage response, resulting in apoptosis. The direct binding of CLO triphosphate metabolites to proteins in the mitochondrial membrane lowers the mitochondrial transmembrane potential and allows the release of proapoptotic factors such as cytochrome *c* and apoptosis-inducing factor (AIF), all of which are important events in the formation of the apoptosome. C-Ara-FdATP is inactivated by cytosolic 5′-nucleotidase and the dephosphorylated metabolites are transported out of the cell.

Pharmacokinetics

The PKs of CLO are affected by age, weight, and creatinine clearance but not by gender, race, or disease type [101]. Adults experience higher CLO exposure than children given a similar dose standardized to body surface area for reasons that are unknown. In a 40-kg patient with a white blood cell count of WBC = 1 × 10^4/μL, CLO has an apparent plasma $T_{½}$ of approximately 6 hours and a volume of distribution of 210 L (72% variability) [101]. There is no reported association between genetic polymorphisms and clinical response to CLO-based therapy, but results from studies with other NAs may be applicable to CLO since similar transporters and metabolic enzymes are involved, and further investigations are warranted.

Adverse effects

Adverse reactions to CLO include myelo- and immunosuppression, infection, hyperuricemia due to tumor lysis, systemic inflammatory response syndrome, hepatic and renal impairment, and GI disorders. In several transplant regimens, CLO potentiates cutaneous toxicity and palmar–plantar erythroderma. CLO should not be used in patients who are pregnant or breast-feeding or who have serious hepatic or renal dysfunction. Some patients may experience nephrotoxicity at conventional dosing when the drug is given as monotherapy for AML. Clinical observations suggest, however, that vigorous hydration may alleviate most of the renal stress, and it is likely possible to use one such (subclinically) nephrotoxic agent without problems. If two or more such agents (e.g., CLO and Mel) are combined, however, the available clinical experience suggests that there may be an excessive risk for renal complications [44].

Drug interactions

CLO should preferably not be administered with other nephrotoxic and hepatotoxic drugs. It may enhance the effects of leflunomide and natalizumab. Tacrolimus, pimecrolimus, and roflumilast may increase the immunosuppressive effects of CLO.

Conclusion

Bifunctional DNA-alkylating agents are still a cornerstone in high-dose chemotherapy, but they are increasingly complemented with NAs, (monoclonal) antibodies, and other agents with alternative modes of action and different metabolism to improve both treatment efficacy and patient safety. Results of recent pharmacogenetic and PK investigations offer opportunities to predict and assess treatment response and side effects better based on patients' unique genotypic profiles and increasingly offer the prospect for individualizing/personalizing treatment. The several-fold variability in metabolism and disposition of cytotoxic agents, as exemplified with busulfan and cyclophosphamide, likely resides in a multitude of factors including, but not limited to, the varying isoenzyme patterns within the GST and CYP protein families, which are of importance for the metabolic handling of these drugs. Several of the (newer) agents are excellent substrates for the trans-membrane transport proteins belonging to the general classes of P-glycoproteins (MDR/MRP) and ABC transporter proteins, whereas there appears to be (at most) very modest involvement of the hepatic CYP P450 pathways in their metabolic disposition. These findings underline that personalized, optimally individualized treatment should preferably include genetic studies of both the patient and the tumor. Such genetic-based studies are over time likely to be followed by a shift to whole-genome-based investigations of drug-associated markers to follow treatment response and detect early surrogate markers of toxicity that may contribute to individualized treatment, thereby further improving the efficacy of the high-dose chemotherapy regimens.

It cannot be overemphasized that inter-individual variations in the PKs of any (antineoplastic) drug are significant. Such variability has to be countered in several ways. First, it justifies the incorporation of pharmacogenetic information about metabolic drug handling. Pharmacogenetic studies are extremely important to increase our understanding of both wanted and unwanted cytotoxic effects. Second, population-genetic studies cannot, however, replace TDM with PK-guided dose adjustments, since the concomitant use of other medications may modify cytotoxic agent PKs, thereby adding an unpredictable component that influences overall drug effect(s). Therefore, the interindividual variability in clinical PKs supports the implementation of PK-guided therapeutic drug delivery to optimize systemic drug exposure. The TDM will assist in circumventing the uncertainties contributed to by both pharmacogenetic differences and by the use of various concomitant medications. It is likely that TDM in the near future will be recognized as being important for optimizing systemic drug exposure and improving the efficacy and safety of high-dose chemotherapy for agents beyond busulfan. Third, combinations of drugs from different classes, with different mechanisms of cytotoxicity, will contribute to improving the therapeutic activity and overcome inherent and/or acquired cellular drug resistance. Healthcare providers should, however, be aware of the peril of possible drug interactions that may sacrifice therapeutic efficacy or result in excessive toxicity. In addition to studying clinical pharmacology, a detailed understanding of the mechanisms of antitumor activity and cytotoxic mode of action at the cellular and molecular level will assist in designing treatment regimens that further improve outcome. For instance, optimizing the sequence of drug exposures may significantly enhance the synergistic activity of the cytotoxic agents. Ultimately, it is through a better understanding of all aspects of the pharmacology of these agents that more effective regimes can be devised without sacrificing patient safety.

CHAPTER 20

High-dose Preparatory Regimens

William I. Bensinger
Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Introduction

Treatment regimens are administered directly prior to hematopoietic cell transplantation (HCT) with two goals, which vary according to the patient's disease and the source of the graft. Since the majority of autologous and allogeneic transplant procedures are performed for the treatment of malignant diseases, the regimens must provide tumor cytoreduction and ideally disease eradication. The pharmacologic basis for this is discussed in Chapter 19. In the case of allogeneic transplants, the regimen must be sufficiently immunosuppressive to overcome host rejection of the graft. This second goal is discussed in detail in Chapter 9.

This chapter reviews high-dose chemotherapy and chemoradiotherapy regimens administered prior to autologous, syngeneic, or allogeneic hematopoietic cell infusion. Most of the high-dose regimens described have been utilized for patients with hematologic malignancies. Some high-dose regimens, however, have been developed specifically for patients with solid tumors, including sarcomas and germ-cell tumors. The overall results of HCT utilizing these high-dose treatment regimens are discussed in more detail in chapters dealing with specific diseases.

The success of HCT as curative therapy for patients with malignancy is limited, in part, by transplant-related morbidity and mortality. Even if all transplant-related problems were to be solved, however, about half (range 10–90%) of patients receiving transplants for various stages of malignant diseases would die owing to the inability of high-dose regimens to eradicate malignancy. This has led to intensive efforts to develop more effective high-dose regimens.

Evaluation of new treatment regimens

The development of new treatment regimens has, in general, required the empirical evaluation of a variety of drugs and radiation doses and schedules. Attempts have been made to systematize the development of new treatment regimens by performing phase I dose-escalation trials followed by phase II trials to estimate potential efficacy. Promising new regimens in ideal circumstances are then compared with established treatment regimens in randomized phase III trials. The methodology for trial design is discussed in more detail in Chapter 27.

Marrow ablative agents – maximum tolerated dose (MTD) when administered with HCT (Table 20.1)

Total body irradiation (Tables 20.1–20.4)

Total body irradiation (TBI) is a widely used therapy for autologous and allogeneic HCT for patients with hematologic malignancies. TBI has retained wide usage over the past 40 years because of excellent immunosuppressive properties, activity against a wide variety of malignancies even if resistant to chemotherapy, penetration of sanctuary sites such as the central nervous system (CNS) and testicles, and the relative lack of non-marrow toxicities when given at high doses.

Only a single study has evaluated TBI alone [1] while other trials have involved the concomitant administration of cytotoxic agents, usually cyclophosphamide (CY). Extensive experience has been accumulated with 10–16 Gy of TBI given as a single dose or fractionated, following or preceding high doses of CY (Tables 20.1–20.3).

A large body of experimental data has been acquired concerning methods to improve the therapeutic index of TBI [2]. Larger doses of TBI that might reduce the likelihood of relapse are limited by gastrointestinal (GI) and pulmonary toxicity, and in the long term by impaired growth and development, chronic pulmonary insufficiency, and second malignancies. In addition to the total dose, many factors, including radiation exposure rate, dose per fraction, interval between fractions, and radiation source (cobalt-60 or linear accelerator), have effects on efficacy and toxicity [2] (see Chapter 22). Many of the techniques of hyperfractionation were developed at the Memorial Sloan Kettering Center [3].

Experimental studies and clinical trials indicate that TBI administered in fractions is more tolerable than single-dose administration and that fractionation, if compensated for by increased total dose, can be given without compromising antitumor effects. Based on this principle, the use of fractionated TBI regimens has been explored in several centers, but there is a paucity of controlled studies of acute and delayed toxicities or of clinical efficacy compared with single-dose TBI. Two prospective randomized studies of fractionation versus single-dose TBI have been performed. One trial demonstrated clear superiority in event-free survival (EFS) following a fractionated regimen in patients with acute myeloid leukemia (AML) transplanted in first remission [4] (Table 20.3).

The second trial was performed in patients with a variety of hematologic malignancies undergoing autologous or allogeneic HCT. Although the patients who received hyperfractionated TBI showed a trend towards better survival and a lower rate of relapse

[a] 5 Gy at 50 cGy/min × 1 or 12 Gy in six fractions.

than patients receiving single-fraction TBI, these differences were not statistically significant [5]. Other studies suggest that fractionation decreases the incidence of idiopathic interstitial pneumonia syndrome (IPS) (Chapter 95) and cataracts (Chapter 103). Not surprisingly, a meta-analysis found that the lung dose of irradiation correlated with the incidence of interstitial pneumonitis [6]. A baseline incidence of 3–4% without radiation increased to a 50% incidence of interstitial pneumonitis with a lung dose of 10.6 Gy. Other groups have utilized reduced yet ablative doses of TBI such as 8 Gy given in four fractions with fludarabine (120 mg/kg) for patients with myeloid leukemias, with good reported efficacy and reduced transplant mortality [7].

Of interest, one center has reported results of high dose rate (30 cGy/min) single-fraction TBI (5.5 Gy) combined with CY for patients with AML undergoing allogeneic transplants from unrelated donors [8]. Transplant mortality was low (13%) for patients in first remission but 41% for more advanced disease. The leukemia-free survival at 3 years was 55% for patients in first remission, similar to that in other reports with higher total doses of irradiation. Although not proven, the antileukemic effectiveness of this lower dose appears to be a consequence of the relatively high dose rate. This same regimen, however, was associated with a high rate of graft rejection when used as a conditioning regimen for patients with chronic myelogenous leukemia (CML) transplanted from unrelated donors [9].

Studies suggest that both the antileukemic effects and normal tissue toxicities of TBI have a relatively steep dose–response curve. In studies of patients with AML in first remission or CML in stable phase, patients receiving 15.75 Gy had a markedly decreased actuarial incidence of relapse compared with patients given 12 Gy. In the CML trial the effect was profound enough to reduce relapse-free survival (RFS) [10].

In studies examining the effect of escalating doses of hyperfractionated TBI at 2.0 Gy given twice daily, the MTD was 16.0 Gy [11]. When 1.2 Gy was given three times per day, however, the MTD was only 14.4 Gy [12], suggesting that the shorter interval between doses of TBI prevented DNA repair in normal tissues.

In the past, most of the TBI regimens used in Seattle have utilized dual opposing ^{60}Co sources. This approach has the advantage of providing highly homogeneous radiation exposure and allows the patient some freedom of movement. However, it is difficult to shield organs, and radiation can be delivered only at relatively low exposure rates (8 cGy/min). Currently, all marrow transplant teams use linear accelerators to deliver TBI (see Chapter 22). With a linear accelerator, dose rates of 40 cGy/min or higher can be administered. The use of linear accelerators may have additional benefits as the radiation field can be shaped with the use of lung shielding to reduce pulmonary toxicity. Electron beam radiation can also be delivered to the chest wall and spine to compensate for the lower dose of TBI to these shielded areas [13]. Shielding of other organs, such as the liver, may be useful if specific organ toxicity limits further increases in TBI dose. Delivery of TBI with shielding of both lung and liver may be useful in patients with disease limited to bone, such as multiple myeloma, breast cancer, and Ewing sarcoma [13].

High-dose chemotherapy regimens (Tables 20.5–20.9)

There have been extensive efforts to develop non-TBI-containing transplant regimens. One of the reasons for pursuing this line of research is that many patients with Hodgkin disease or lymphoma

BCNU, carmustine.

[a] Each drug given on a separate day with 1 day's rest between.

have received prior dose-limiting radiotherapy, especially to the mediastinum, which results in a high incidence of fatal IPS following TBI [14]. Chemotherapy regimens may also avoid the long-term sequelae of TBI, including cataracts, sterility, second malignancies, and growth and development problems in children. In addition, there has recently been concern about the development of myelodysplasia and AML, although this risk appears to be limited to autologous HCT, since allogeneic HCT usually eliminates damaged stem cells through the graft-versus-leukemia (GVL) reaction [15].

There are potential advantages in terms of convenience and expense of moving away from TBI, in that TBI utilizes already over-extended radiation resources, often for prolonged periods of time, and requires the skills of physicists and radiotherapists. Finally, it may be possible to develop chemotherapy regimens that are more effective than those containing TBI. It is unfortunate that there are at present few studies comparing outcomes of specific regimens used for HCT.

Alkylating agents

Alkylating agents are the major class of drug used in high-dose regimens with HCT support because they have several desirable characteristics. Many alkylating agents have marrow toxicity as the major dose-limiting factor, which allows for dose escalation when hematopoietic cells are utilized. Alkylators are not cell cycle specific, making them capable of killing non-dividing, resting tumor cells. In in vitro testing, alkylators do not generally exhibit cross-resistance and have relatively steep log-linear dose–response curves [16]. Although it is not possible to combine alkylating agents at full dose when used alone, between 50% and 70% of the single-agent MTD can be used in two to three drug combinations.

As regimens for the treatment of solid tumors evolve, there has been movement to incorporate tumor-specific drugs into the high-dose therapy setting. It is important to point out, however, that drugs such as mitoxantrone and paclitaxel, which are highly active against tumors such as breast or ovarian cancer at conventional doses, are more difficult to deliver at higher doses owing to non-hematologic toxicities, that is, cardiac or neurologic. These characteristics limit the usefulness of such drugs in high-dose therapy regimens, and their value in comparison with alkylator-based regimens remains to be proven.

Busulfan (Tables 20.1 and 20.5)

Busulfan (BU) is an alkylating agent with profound myeloablative properties and marked activity against non-dividing marrow cells, and possibly non-dividing malignant cells also. The MTD of BU, given as a single agent over 4 days followed by stem-cell support, is approximately 20 mg/kg [17]. Single-agent testing to determine the spectrum of activity in patients with malignant disease has not been extensive. However, BU is probably active in a variety of malignancies, including multiple myeloma [18], lymphoma [19], acute lymphoblastic leukemia (ALL) [19], AML [20], myelodysplasia [21], testicular tumors [22], and Ewing sarcoma [22].

One of the earlier problems with optimal utilization of BU had been the availability of only the oral form. Pharmacokinetic variability between patients is high, with a 2–3-fold difference in plasma levels between patients [23]. When given a set oral dose of BU (16 mg/kg over 4 days), children have lower mean plasma levels of BU (650 ng/mL) than adults (1050 ng/mL) [24], which may be partially compensated for by dosing children by body surface area rather than weight [24]. Variation in BU plasma levels between individuals probably contributes to the significant differences in toxicity and clinical response observed in patients receiving the same mg/kg or mg/m^2 dose. Slattery et al. demonstrated a relationship between low BU steady-state plasma concentrations and graft rejection in children [24]. There are also data suggesting a direct relationship between the severity of regimen-related toxicity (RRT), especially sinusoidal obstruction syndrome (SOS) of the liver, and high BU plasma levels [25]. This is discussed in more detail in the section on hepatic complications after transplantation in Chapter 95. In a patient accidentally overdosed with BU, hemodialysis resulted in accelerated clearance of the drug [26].

It has been shown that the steady-state BU concentration correlates with relapse in patients receiving human leukocyte antigen (HLA)-compatible transplants for CML in chronic phase [27]. Seven relapses occurred among the 22 patients with BU state concentrations below the median of 918 ng/mL compared with none among the 23 patients at or above the median ($p < 0.0003$).

Hence the average steady-state concentration of BU over a 4-day period may be a more important determinant of toxicity and efficacy than the exact mg/kg or mg/m^2 dose administered to any given patient [27]. Fortunately, within a given patient, BU is a pharmacokinetically predictable drug, and its absorption and elimination rate remain linear over a wide dose range and constant with time [24]. With repeated oral administration, steady-state BU plasma concentrations are achieved rapidly and can be predicted from first-dose kinetics. Following determination of first-dose kinetics, oral doses can be adjusted up or down to achieve the desired plasma levels. The strategy of targeted steady-state BU dosing has been used successfully to perform a dose-escalation trial in patients receiving fixed doses of CY and TBI [28]. Targeting of the steady-state plasma level of BU should increase the therapeutic index. Results of phase 2 studies indicated that targeting oral BU in patients with CML, AML, and myelodysplasia is associated with low transplant-related toxicity and a low relapse rate [29].

An intravenous preparation of BU is available, and phamacokinetic data indicate considerably less individual variation in area under the curve (AUC) values than seen with the oral preparation [30]. Intravenous BU can be given as a single daily dose over 3 hours or twice daily rather than as the usual four oral doses per day [31]. Retrospective comparisons of intravenous BU with oral BU suggest less hepatic toxicity in patients receiving the intravenous form.

A regimen of BU combined with CY has been developed that has had a wide application for the treatment of a variety of malignant and non-malignant diseases using autologous and allogeneic stem-cell support [32]. The original regimen included BU 4 mg/kg/day for 4 days followed by CY 50 mg/kg/day for 4 days. This regimen was subsequently modified by lowering the dose of CY to 120 mg/kg, with an apparent decrease in toxicity without an increase in relapses [33]. It has been reported that 16 mg/kg combined with 120 mg/kg CY results in prohibitive toxicity in older patients with multiple myeloma and breast cancer undergoing autologous or allogeneic transplantation [18]. Although these reports could be due to small numbers of patients with advanced disease, lowering the dose of BU to 14 mg/kg decreased toxicity and allowed for an increase in the dose of CY to 150 mg/kg. It has also been shown that older patients with CML or myelodysplastic syndrome tolerate targeted BU and CY 120 g/kg fairly well [34]. In patients with thalassemia, BU 14 mg/kg followed by CY 120–200 mg/kg has been a well-tolerated and effective regimen for allografting. A randomized trial comparing BU dosed at 600 mg/m^2 with BU dosed at 16 mg/kg for patients receiving transplant for thalassemia found no differences in outcome but, not surprisingly, that rejection occurred mainly in patients with low blood levels of BU [35]. Fludarabine, a nucleoside analog with significant immunosuppressive activity, has been substituted for CY in an effort to reduce RRT. In addition, fludarabine inhibits DNA repair and thus is synergistic with alkylators that cause breaks in the DNA strand. Several trials conducted in patients with myeloid leukemias undergoing allogeneic HCT indicate lower toxicity profiles with fludarabine–BU combinations [36].

Etoposide (60 mg/kg) has also been utilized to replace CY in the BU–CY regimen for the treatment of patients with AML undergoing autologous bone marrow transplantation, with encouraging disease-free survivals [37]. The major toxicities, SOS, mucositis, and skin breakdown, are similar to those described with BU + CY or BU + melphalan (MEL).

BU (16 mg/kg) and MEL (140 mg/m^2) have been combined and evaluated in patients undergoing autologous or allogeneic HCT for a variety of hematologic malignancies [38]. MEL (180 mg/m^2) has also been combined with fludarabine (125 mg/m^2) as an unrelated donor conditioning regimen for patients with hematologic malignancies [39].

A regimen of BU (12 mg/kg), MEL (100 mg/m^2), and thioTEPA (500 mg/m^2) followed by autologous HCT has been evaluated in patients with a variety of malignant diseases [40]. This regimen produces profound marrow ablation with significant mucositis and is associated with an approximately 5% treatment-related mortality due to IPS. Regimens involving BU, thioTEPA, and CY have been utilized for auto- [41] and allografting. A regimen involving BU, CY, and etoposide has been utilized prior to an autologous and allogeneic HCT [42].

Treosulfan (dihydrobusulfan) (30–42 g/m^2) has been substituted for BU in combination with fludarabine, CY, or MEL as an allogeneic preparative regimen for patients with both myeloid and lymphoid malignancies [43]. This regimen may be associated with less RRT and a lower early transplant-related mortality; however, a retrospective study comparing fludarabine, treosulfan with fludarabine, and myeloablative or non-ablative doses of BU found no significant differences in survival among patients with less advanced disease [44]. More recently, clofarabine, a second-generation analog of 2′-deoxyadenosine combining properties of cladribine and fludarabine, has been combined with BU to form an allogeneic transplant regimen in patients with refractory AML [45].

Nitrosoureas (Tables 20.1 and 20.6)

Carmustine [1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU)] is a nitrosourea commonly used as a marrow ablative agent because it is active against a variety of tumors [46]. The active metabolite of BCNU is a chloroethyl carbonium ion produced by hydrolysis. It is highly lipid soluble and has been used extensively for the treatment of malignant brain tumors. In conventional doses, BCNU is limited by delayed marrow toxicity, pulmonary fibrosis, and renal dysfunction. The MTD, as a single agent, is 120 mg/m^2 when given with autologous stem-cell infusions. The dose-limiting toxicities are pulmonary and hepatic [46]. When BCNU is used in combinations that include cisplatin and CY, there is a substantial increase in the risk of lung injury [47]. When carboplatin and CY are added to BCNU, a high rate of veno-occlusive disease has been reported [48].

BCNU and CY are often combined and may have synergistic activity. The first multidrug transplant regimen consisted of a combination of BCNU, cytarabine, CY, and thioguanine (BACT) [49]. Variations of these drugs have evolved into the three- and four-drug combinations in common use today involving BCNU.

Regimens containing CY, BCNU, and etoposide (CBV) have been evaluated extensively in patients with malignant lymphoma receiving autologous transplants [50]. The doses of drugs and the schedules are shown in Table 20.6. These regimens are often used as substitutes for TBI-based regimens for patients with lymphoma who have received prior dose-limiting irradiation [51]. Doses of BCNU exceeding 450 mg/m^2 are associated with unacceptable pulmonary toxicity [52]. Early institution of steroid therapy at the first sign of dyspnea may prevent the more serious and often fatal complication of pulmonary fibrosis [47]. Patients who receive high-dose BCNU should receive close long-term follow-up for pulmonary complications, which have been noted in adults who received large doses of BCNU as children [53]. Less frequent severe toxicities include SOS, hemorrhagic cystitis, and nephrotoxicity. Although not extensively evaluated, all of these combinations are probably sufficiently immunosuppressive to achieve allogeneic engraftment. Lomustine has been substituted for BCNU in an attempt to decrease pulmonary toxicities, but without a clear reduction in lung complications [54].

BCNU, etoposide, cytarabine, and CY (BEAC) have been extensively evaluated for patients with malignant lymphoma [55]. MEL has been substituted for CY in the BEAC regimen to create BEAM and has also been extensively evaluated in patients with malignant lymphoma [56]. Since most patients with malignant lymphoma have peripheral blood hematopoietic cells (PBHCs) collected after CY-containing regimens, the BEAM regimen may be more attractive than the BEAC regimen. Furthermore, the substitution of MEL for CY obviates the problem of cystitis and the need for mesna (sodium 2-mercaptoethanesulfonate) and/or bladder irrigation, making this a preferred outpatient regimen for patients with malignant lymphoma. Allogeneic marrow transplants also have been performed following the administration of BEAM [57].

Melphalan (Tables 20.1 and 20.7)

One of the earliest chemotherapeutic agents developed, MEL is a bifunctional alkylating agent whose structure incorporates nitrogen mustard and phenylalanine [58]. Single doses of MEL, 150–240 mg/m^2, followed by autologous stem-cell infusion, have been evaluated in patients with multiple myeloma and breast cancer with the dose-limiting toxicities being GI and hepatic [59,60]. MEL 240 mg/m^2 has been utilized alone as a conditioning regimen for patients with hematologic malignancies receiving allogeneic transplants from HLA-matched siblings [61]. MEL has been widely used in high-dose regimens for patients with breast and ovarian cancer, multiple myeloma, or lymphoma. MEL 100 mg/m^2 has been used as a reduced-intensity conditioning regimen prior to allogeneic stem-cell transplantation in patients with multiple myeloma [62]. Fludarabine has been combined with MEL to form a reduced-intensity regimen for allografting [39].

MEL is utilized alone or with TBI to treat patients with multiple myeloma [63] or leukemia. A randomized trial of single-agent MEL (200 mg/m^2) compared with reduced-dose MEL (140 mg/m^2) with TBI as a preparative regimen for patients with myeloma demonstrated a survival advantage for MEL alone [63]. As a result, single-agent MEL is by far the most commonly used conditioning regimen for patients with myeloma undergoing autologous peripheral blood HCT. Recent efforts have been made to improve on MEL monotherapy, including escalating doses to 280 mg/m^2 using palifermin or amifostine as cytoprotective drugs [64,65] or by the addition of bortezomib to MEL 200 mg/m^2 [66].

MEL is included in several of the BU- and BCNU-based regimens listed in Tables 20.5 and 20.6, and Table 20.7 summarizes additional regimens that have included MEL for myeloablation. MEL is frequently combined with BCNU (BEAM), a regimen utilized for patients with malignant lymphoma [56]. BEAM itself has been modified by substituting bendamustine for BCNU [67] or by adding fludarabine and TBI to an allograft regimen [68].

ThioTEPA (Tables 20.1 and 20.8)

ThioTEPA was first recognized for its antitumor properties in the 1950s, but because of severe myelosuppression it saw only limited use in breast and ovarian cancer. Both thioTEPA and its major metabolite TEPA (*N*-triethylenephosphoramide) are active against tumor cell lines *in vitro*. The plasma half-life of TEPA is much longer than that of thioTEPA and accounts for much of the clinical toxicity. ThioTEPA crosses the blood–brain barrier and is useful in the management of CNS disease. It is also fairly immunosuppressive and has been used in preparative regimens to reduce graft rejection in T-cell-depleted allogeneic HCT. The MTD for thioTEPA, as a single agent with stem-cell support, is approximately 1100 mg/m^2. Dose-limiting toxicities are of the CNS, GI tract, liver, and skin [69].

ThioTEPA is included in several of the above BU-, BCNU- and MEL-based regimens outlined in Tables 20.5–20.7, and Table 20.8 summarizes additional regimens that include high doses of thioTEPA.

Non-marrow ablative agents and agents for which MTD with stem-cell support is not known

Cyclophosphamide (Table 20.1)

CY alone was originally used to achieve allogeneic engraftment in patients with aplastic anemia and hematologic malignancies, but was modified in patients with malignant disease by the addition of TBI or combinations of chemotherapeutic agents. However, CY, with or without antithymocyte globulin, is still the most commonly used regimen for immunosuppression of patients with aplastic anemia prior to allogeneic transplantation. Low doses of TBI (2–5 Gy) have been added to CY as a conditioning regimen for aplastic anemia in an effort to increase immunosuppression and reduce episodes of graft rejection [70]. CY is very immunosuppressive but is not marrow ablative as the dose-limiting toxicity is hemorrhagic myocarditis. The MTD, as a single agent, is approximately 200 mg/kg, and infusion of marrow has no impact on survival at this or higher doses [71]. Stem cells are believed to be resistant to CY because they express high levels of aldehyde dehydrogenase. The major side effect, at doses of 120–200 mg/kg, is hemorrhagic cystitis, which can be diminished by bladder irrigation or the administration of mesna. While hemorrhagic myocarditis is a dose-limiting toxicity. CY can temporarily affect cardiac function leading to congestive failure. This is often first noticed by low voltage on the electrocardiogram. Both CY and its isomer ifosfamide have been extensively utilized with high-dose chemotherapy regimens for most tumor types treated with HCT.

Ifosfamide (Table 20.1)

Ifosfamide, a structural isomer of CY, has been evaluated in high-dose regimens followed by autologous stem cells as a substitute for CY. Similarly to CY, however, hematopoietic toxicity is not dose limiting even when high doses of ifosfamide are administered [72]. The MTD is 18–20 g/m^2 with the dose-limiting toxicities being renal, bladder, and neurologic, with lethargy, confusion, and seizures. Ifosfamide is always given with mesna for bladder protection. Ifosfamide is frequently combined with carboplatin and etoposide (ICE) for the treatment of lymphoma, but this regimen does not require HCT [73].

Etoposide (Tables 20.1 and 20.9)

Etoposide is a semisynthetic derivative of podophyllin. It appears to act by stabilization of the topoisomerase II–DNA complex, with subsequent DNA breaks and cell-cycle arrest. This mechanism of action may promote synergistic cell killing when combined with alkylators [37]. The MTD for etoposide, as a single agent with stem-cell support, is approximately 2400 mg/m^2. Although etoposide has substantial myelotoxicity, the dose-limiting toxicity is to the GI tract. In a phase I study with marrow support, the tempo of recovery of peripheral counts was not related to the dose of etoposide and was more rapid than recovery after TBI regimens with marrow support [74].

Etoposide is commonly used with TBI [75] in the regimens listed in Tables 20.6 and 2.7, and additional regimens are outlined in Table 20.9. It is not clear whether any of the regimens in Table 20.9 requires HCT. BU has been combined with etoposide (Table 20.5), resulting in a unique HDT regimen that is particularly active in patients with acute leukemias [37]. The major dose-limiting toxicities of this regimen are GI and pulmonary.

Fludarabine

Fludarabine, a purine analog, has been widely incorporated into non-myeloablative transplant regimens because it is profoundly immunosuppressive and can facilitate engraftment with low-intensity regimens. More recently, fludarabine has been added to marrow ablative doses of busulfan, as a substitute for CY in order to develop a high-intensity regimen that is less toxic [44]. Fludarabine and sub-myeloablative doses of MEL are also utilized as an allograft preparative regimen [39].

Mitoxantrone (Tables 20.1 and 20.7) and doxorubicin (Table 20.9)

Mitoxantrone has been utilized in a variety of high-dose regimens, but the MTD as a single agent with stem-cell support has not been reported [76]. Single-agent dose-escalation trials in patients with metastatic breast cancer have been limited by cardiac toxicity and are disappointing in terms of response rates. The highest dose of mitoxantrone administered in a high-dose combination regimen has been 90 mg/m^2 given with thioTEPA 1200 mg/m^2 [77].

Regimens including mitoxantrone are included in Tables 20.7 and 20.8. In one study, CY 7 g/m^2 and escalating doses of mitoxantrone led to unacceptable hemorrhagic cystitis despite mesna, leading the investigators to substitute MEL for CY [78].

In a similar fashion, doxorubicin, a compound structurally related to mitoxantrone, has been combined with etoposide and CY as a high-dose regimen for patients with breast cancer [79]. The MTD of doxorubicin was 165 mg/m^2, with the dose-limiting toxicity being mucositis. It is not clear that the use of mitoxantrone or doxorubicin in high-dose regimens requires stem-cell support, and it remains to be determined whether such anthracycline-based regimens are more efficacious than alkylator-based combinations. There is significant controversy as to whether high-dose regimens of any kind are useful for patients with high-risk or metastatic breast cancer.

Cisplatin (Table 20.1)

The MTD for cisplatin as a single agent with HCT has not been reported, and the highest dose given in combination regimens has been 300 mg/m^2 given with etoposide 60 mg/kg and CY 100 mg/kg [80].

Regimens including cisplatin are outlined in Tables 20.6–20.9. Although limited by nephrotoxicity and ototoxicity when utilized as a single agent, when used with other drugs the doses of cisplatin do not exceed 200 mg/m^2 and, with adequate hydration, renal dysfunction is generally avoidable.

Carboplatin (Table 20.1)

The MTD for carboplatin with HCT is approximately 2000 mg/m^2, with the dose-limiting toxicities being hepatic and renal [81]. Carboplatin in conventional doses is usually given in line with a formula based on renal function. However, Shea et al. administered carboplatin in doses of 375–2400 mg/m^2 and found a direct correlation between the dose and the measured AUC, suggesting that high doses could be based on body surface area. Carboplatin has also been combined with etoposide, CY, and escalating doses of TBI (10–12.9 Gy) for the treatment of a variety of hematologic malignancies [82]. In one study, carboplatin was administered at doses of 1000–1600 mg/m^2 in conjunction with high doses of MEL and mitoxantrone. In a retrospective analysis of this study, dosing by the Calvert formula was more predictive of grade 3–4 toxicities than dosing by body surface area. These data suggested that dosing of carboplatin to an AUC of 20 mg/mL/min rather than 1400 mg/m^2 would decrease grade 3–4 RRT in patients receiving MEL (160 mg/m^2) and mitoxantrone (50 mg/m^2) followed by PBHC infusion [83].

High-dose chemotherapy regimens including carboplatin are outlined in Tables 20.7–20.9. A phase I–II trial determined that the MTDs of carboplatin and CY administered together are 1.8 and 6.0 g/m^2, respectively [84]. Carboplatin (1500 mg/m^2) with CY (120 mg/m^2) and mitoxantrone (75 mg/m^2) appears to be an active regimen for the treatment of patients with ovarian cancer [85]. Combinations of carboplatin, etoposide, and either paclitaxel or thioTEPA are used with HCT support for the treatment of germ-cell tumors [86].

Cytarabine (Table 20.1)

Cytarabine is a cell cycle-specific antineoplastic agent that affects cells only in S-phase. Although its mechanism of action is not fully understood, its metabolite cytarabine triphosphate is believed to inhibit the action of DNA polymerase. It may also function as a false substrate when incorporated into DNA. The MTD of cytarabine when administered as a single agent with HCT has not been determined. However, in combination with other agents given in high doses, cytarabine is usually administered in doses of 3 g/m^2 for 4–12 doses at 12-hour intervals [87]. Cytarabine 12–36 g/m^2 is included in several regimens utilized for the treatment of patients with hematologic malignancies, as outlined in Tables 20.6 and 20.7.

Paclitaxel

Paclitaxel is an antimicrotubule drug that facilitates microtubule assembly from tubulin dimers and stabilizes microtubules by preventing depolymerization. This stabilization inhibits microtubule reorganization, preventing progression to mitosis. Paclitaxel 775 mg/m^2 has been substituted for BCNU in a regimen including 5.6 mg/m^2 CY and 165 mg/m^2 cisplatin [88]. Paclitaxel 500–700 mg/m^2 has been administered with MEL (180 mg/m^2) and mitoxantrone (60–90 mg/m^2) to patients with advanced ovarian cancer (Table 20.8) [89]. Paclitaxel 150–775 mg/m^2 has also been combined with doxorubicin (165 mg/m^2) and CY (100 mg/kg) and utilized for patients with advanced breast carcinoma [90].

High-dose regimens with total body irradiation

Total body irradiation with cyclophosphamide (Table 20.2)

The use of CY with TBI is based on empirical observations. CY (120 mg/kg) was originally given prior to TBI to a patient undergoing a syngeneic marrow transplant for advanced lymphoma in 1970 in order to avoid tumor lysis and acute renal failure that had been previously observed with TBI given in a single dose of 10 Gy. CY is regularly given prior to TBI in patients receiving allogeneic or syngeneic marrow transplants with no apparent excess toxicity over that observed following TBI alone and hence has become a "standard regimen" widely used in many transplant centers. Although several agents have been added to or substituted for CY (Table 20.4), most of the TBI regimens tested over the past 20 years have included CY before or after TBI. A variety of TBI regimens have been evaluated in attempts to define an optimal dose and schedule. Table 20.2 summarizes the MTDs for several different schedules of TBI (delivered by ^{60}Co sources at dose rates of 5–10 cGy/min) given after CY 120 mg/kg.

Randomized trials involving different TBI regimens (Table 20.3)

There has been a paucity of randomized controlled trials evaluating different TBI regimens (Chapter 22). Three trials reported by the Seattle Marrow Transplant Team are summarized in Table 20.3 [4,10,91].

Total body irradiation with drugs other than cyclophosphamide (Table 20.4)

Drugs other than CY have been administered with TBI, as shown in Table 20.4, but there is no evidence that any of these agents is superior to CY when given with TBI since randomized controlled trials have not been performed. When BU was substituted for CY given with 12 Gy TBI as allograft conditioning for patients with myelodysplastic syndrome, the toxicities were considerable with a day 100 non-relapse mortality of 38% [92]. A large, retrospective analysis of patients reported to the International Bone Marrow Transplant Registry compared outcomes of two regimens used for allografting from HLA-identical siblings for patients with ALL in first or second remission [93]. All 502 patients received myeloablative doses of TBI with either CY (*n* = 298) or etoposide (*n* = 204). There were no differences in outcomes by regimen for patients in CR1 (complete remission 1); however, for patients in CR2, there was a lower risk of relapse and mortality when etoposide was used with any TBI dose when compared with CY and TBI doses below 13 Gy.

Cyclophosphamide and total body irradiation with other drugs (Table 20.4)

Other agents have been combined with CY and TBI, as shown in Table 20.5. Phase II trials suggest that many of these combinations may have better therapeutic efficacy than CY/TBI, but none of these regimens has been subjected to randomized comparison studies.

High-dose chemotherapy versus high-dose chemoradiotherapy (Table 20.10)

There have been relatively few studies comparing chemotherapy regimens with TBI-based regimens. Two randomized trials have demonstrated the equivalency of BU/CY and CY/TBI in patients with CML in chronic phase receiving HLA-matched allografts [94,95]. One study in patients receiving HLA-compatible transplants for AML showed superiority for the CY/TBI regimen due to a lower relapse rate [96]. The Southwest Oncology Group compared

Table 20.10 Randomized trials of BU/CY versus TBI ± VP16 ± CY

Ref.	Diagnosis	Regimen	No.	Survival	Relapse	Event-free survival
[96]	AML	BU/CY	51	0.51	0.34	0.47
		CY/TBI	50	0.75	0.14	0.72
[95]	CML	BU/CY	65	0.61	0.44	0.59
		CY/TBI	55	0.63	0.11	0.55
[94]	CML	BU/CY	73	0.80	0.13	0.68
		CY/TBI	69	0.80	0.13	0.71
[132]	"Advanced" leukemias	BU/CY	61	0.30	NR	0.20
		VP-16/TBI	61	0.30	NR	0.20
[101]	ALL (pediatric)	TBI/VP16/CY	22	0.45	NR	0.58
		BU/VP16/CY	21		NR	0.29

AML, acute myeloid leukemia; BU, busulfan; CY, cyclophosphamide; NR, not reported; TBI, total body irradiation.

BU/CY with etoposide/TBI in 122 patients with advanced acute leukemias or CML beyond first chronic phase undergoing matched allogeneic transplantation. There were no significant differences in toxicity, acute graft-versus-host disease (GVHD), survival, or disease-free survival in patients entered on either regimen [97]. An analysis of non-randomized trials reported by Horning et al. suggested equivalency between patients with lymphoma receiving TBI and etoposide or CBV given prior to autologous transplantation [98]. There were no differences in outcomes seen in a retrospective analysis of a BCNU/etoposide/CY regimen or TBI/etoposide/CY regimen for patients with Hodgkin disease undergoing autologous HCT [99]. A similar non-randomized analysis comparing 381 patients with AML in first remission undergoing allogeneic HCT found no differences in survival between BU/CY and CY/TBI but a lower risk of relapse with CY/TBI [100]. In children with ALL undergoing allogeneic HCT, a small randomized trial demonstrated that BU/etoposide/CY resulted in an inferior event free survival compared with a regimen of TBI/etoposide/CY [101]. In another trial of high-dose cytarabine, MEL, and either BU or fractionated TBI in children with high-risk ALL undergoing allogeneic HCT, BU was associated with fewer long-term side effects [102]. In multiple myeloma, a randomized comparison of MEL 200 mg/m^2 versus MEL 140 mg/m^2 plus 8 Gy TBI demonstrated similar event-free survivals but a superior 45-month overall survival for the MEL monotherapy group, 66% versus 46% [63].

Modified total body irradiation regimens

Because of the considerable toxicities to non-target organs associated with external-beam TBI, there has been interest in the application of technical modifications to TBI. In one early approach, external-beam TBI was given with 90% lung shielding followed by electron beam to the rib cage in order to deliver a uniform dose of radiation to all marrow-bearing areas. This modified TBI was studied in a phase I trial as the second part of a tandem transplant for patients with bone-based malignancies [13]. The MTD in this trial was 13.5 Gy. Another trial combined modified TBI (9 Gy) with BU (12 mg/kg) and CY (120 mg/kg) to treat 89 patients with multiple myeloma [103]. The transplant mortality in this study was 2%, with a complete remission rate of 48%.

More recently, studies have been conducted using image-guided tomographic intensity-modulated radiation equipment that does not require organ shielding. Simulations of dosimetry using this equipment indicate a 1.7–7.5-fold reduction in median doses to non-target organs [104]. Furthermore, this approach may allow a significant escalation of doses of TBI of up to 20 Gy to target organs such as bone.

Marrow ablation using targeted radioisotopes

Some alternatives to the external-beam delivery of radiation using radioimmunotherapy are discussed in more detail in Chapter 23. One approach to improving the cure rate of transplant conditioning regimens while simultaneously decreasing toxicities to normal organs is to replace or augment non-specific external-beam TBI with targeted radiotherapy. Radiolabeled monoclonal antibodies have the potential to focus higher doses of radiation on tumor sites than is possible with external-beam TBI and expose normal organs to lower doses of radiation. Recent evaluations of these techniques have been performed in patients with multiple myeloma, malignant lymphoma, and AML.

Bone-seeking radioisotopes

Isotopes that selectively bind to bone by themselves (yttrium-90) [105], or when complexed to bone-seeking compounds, are an attractive way to target radiation for patients with malignancies in which bone or bone marrow is the primary site of disease. Few studies have utilized radioisotopes alone for marrow ablation. Bayouth et al. performed a phase I trial of holmium-166 (^{166}Ho) complexed to the bone-seeking isotope 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetramethylenephosphonic acid (DOTMP) in patients with multiple myeloma. The total dose of radiation adsorbed that was delivered to the bone marrow for six patients ranged from 7.9 to 41.4 Gy, and marrow ablation requiring the infusion of stem cells was achieved in two patients. In several multicenter phase I–II trials, cohorts of patients with multiple myeloma received increasing doses of ^{166}Ho–DOTMP designed to deliver 20, 30, or 40 Gy to the bone marrow. This was followed by high-dose MEL 140–200 mg/m^2, external-beam TBI (some patients), and peripheral blood hematopoietic progenitor cells [106]. There were no grade 3–4 non-hematologic toxicities within the first 60 days. After 60 days, significant hemorrhagic cystitis occurred at one center that did not use bladder irrigation. Seven patients experienced late thrombotic microangiopathy among the group receiving more than 30 Gy (or 2400 mCi dosed) to the marrow. The complete remission rate was 35%, with a median overall survival in excess of 24 months. Since two-thirds of the patients in these trials had relapsed or refractory disease, this remission rate was higher than would be expected with MEL alone.

Another bone-seeking radioisotope, samarium-153 (^{153}Sm), with less beta energy than ^{166}Ho, has been linked to ethylenediamine tetramethylenephosphonate (EDTMP), a tetraphosphonate chelate, and studied in 46 patients with multiple myeloma who received MEL 200 mg/m^2 following the isotope. Patients received individualized doses of ^{153}Sm designed to deliver 40 Gy to the bone marrow. The treatment was well tolerated and when compared with 102 contemporaneously treated patients who received MEL 200 mg/m^2 monotherapy, outcomes were better than would be expected with MEL alone [107]. The role of bone-seeking isotopes should be expanded over the next several years, and they may become a major therapeutic approach to the treatment of malignancies involving the bone marrow.

Sequential regimens with peripheral blood hematopoietic cell support

The concept of administering tandem high-dose cycles or multiple, less-intensive treatments more frequently as an alternative to single high-dose marrow ablative therapy has only recently been explored. Some groups have utilized tandem cycles of high-dose MEL 200 mg/m^2 or MEL and TBI, followed by autologous stem-cell infusion for the treatment of patients with multiple myeloma. Tandem cycles of MEL produced complete response rates of 44% in patients with myeloma. Several prospective, randomized trials of single- versus double-intensive therapy for patients with multiple myeloma have been reported [108,109]. These trials employed MEL 140–200 mg/m^2 for the first cycle and MEL + TBI or BU for the second cycle. One trial found a survival advantage for the tandem approach whereas the second study showed equivalent survival, but both trials reported better complete response rates and event-free survival favoring the tandem approach.

Tandem cycles of high-dose chemoradiotherapy with CY, etoposide, MEL, thioTEPA, and TBI have been used to treat children with stage IV neuroblastoma [110]. Tandem cycles of paclitaxel, carboplatin, and either etoposide or ifosfamide have been utilized with autologous HCT for relapsed germ-cell tumors [111]. Tandem autologous transplant, MEL (150 mg/m^2) for cycle 1 and CBV or TBI/CY/etoposide for cycle 2, has been utilized to treat patients with primary refractory or relapsed Hodgkin lymphoma [112]. It remains to be determined whether or not this approach will be superior to single high-dose ablative regimens.

Allogeneic transplantation with non-marrow-ablative regimens

There is increasing evidence that stable donor chimerism can be achieved with sub-lethal doses of TBI or chemotherapy and immunosuppressive drugs. Partial, but stable, grafts would be of benefit for patients with non-malignant diseases, such as thalassemia or sickle cell anemia, if they could be achieved without transplant-related mortality. Patients with malignancies are often considered too old for high-dose regimens or, when young enough, have organ dysfunction that precludes administration of intensive regimens prior to allografting. In contrast to non-malignant diseases, however, the successful treatment of cancers with allogeneic transplant almost certainly requires full donor engraftment in order to utilize the GVL effect. It is of major interest to develop non-toxic methods of achieving donor chimerism that would then allow the evaluation of post-transplant immunotherapy with donor lymphocytes, which would then be relied on to produce the bulk of the antileukemic therapy. Non-ablative allografting strategies are discussed in detail in Chapter 21.

Conclusion

Because of the relatively high probability of relapse in many patients receiving HCT, the further development of new treatment regimens is warranted. However, one can predict that it will continue to be difficult to identify more effective treatment regimens. Incremental improvements in treatment regimens are expected to be small and difficult to measure, and will require the study of large numbers of patients. There continues to be a great need for controlled trials to evaluate the effectiveness of specific treatment regimens for specific groups of patients. Only centers with large numbers of patients or cooperative study groups can successfully perform the trials necessary to substantiate the effectiveness of a given treatment regimen. In order to make high-dose therapies and peripheral blood hematopoietic cell support generally available, the procedure will have to be performed with low mortality and minimal morbidity in an outpatient setting. To achieve this goal without sacrificing efficacy, agents that protect normal, non-hematopoietic tissues from RRT may have to be utilized. In addition, studies utilizing targeted radioisotopes may allow further dose intensity to tumor-bearing tissues while sparing non-involved organs.

CHAPTER 21

Reduced-intensity Allogeneic Transplantation Regimens

Brenda M. Sandmaier and Rainer Storb
Fred Hutchinson Cancer Research Center and University of Washington, Seattle, WA, USA

Introduction

Allogeneic hematopoietic cell transplantation (HCT) has an important role in the treatment of malignant and non-malignant hematological diseases. Successful allogeneic HCT must overcome two immunologic barriers: graft-versus-host (GVH) and host-versus-graft (HVG) reactions. The conventional strategy to overcome this bidirectional barrier has relied upon three elements. First, intensive conditioning regimens are delivered with the dual purposes of immunoablation and disease eradication, which consist of otherwise supralethal doses of irradiation and/or chemotherapy. Second, donor hematopoietic cells are given to rescue patients from lethal myeloablation. Third, T-cell depletion or post-grafting immunosuppression is used to control GVH disease (GVHD) and establish long-term graft–host tolerance.

Toxicities related to the conditioning regimens are a major limitation in the application of high-dose HCT. Toxicities include pancytopenia, which sets the stage for life-threatening infections, and damage to the liver, kidneys, and lungs, which may impair the ability to deliver the doses of immunosuppression necessary for control of GVHD. For these reasons, high-dose allogeneic HCTs have been carried out in specialized hospital wards and their use restricted to relatively young patients at most transplant centers.

The concept that conditioning dose intensification was the only approach for eradicating malignancy came into question early in the history of clinical HCT. Findings in the late 1970s and early 1980s drew attention to graft-versus-tumor (GVT) effects, as evidenced by better relapse-free survival in patients with acute or chronic GVHD [1–6]. Additional evidence supporting GVT effects included lower relapse rates among patients who received unmodified allogeneic HCT compared with T-cell-depleted allografts [6], autologous grafts [7,8], or syngeneic grafts [9], and the induction of durable remissions with donor lymphocyte infusions (DLIs) in patients who had relapsed after allogeneic HCT [10–15]. These observations led to the hypothesis that GVT effects might be exploited in patients thought to be too old or medically infirm to tolerate high-dose conditioning regimens. Accordingly, several groups of investigators have developed reduced-intensity regimens that minimize the regimen-related toxicities and rely on GVT effects to treat the underlying malignancies.

The least intensive regimens rely on pre- and post-transplant immunosuppression to establish the allografts. It is important to remember that both HVG and GVH reactions are mediated by T cells of host and donor origin, respectively, when transplants are carried out across minor histocompatibility barriers. From these facts follows the hypothesis that HVG reactions can, to some extent, be controlled through novel and effective agents that at the same time serve to control GVHD. Consequently, much of the toxic high-dose pre-transplant therapy previously employed for HVG control can be replaced by relatively non-toxic immunosuppression. Once established, grafts would create marrow space through subclinical GVH reactions, and cytotoxic and myeloablative doses of total body irradiation (TBI) or busulfan (BU) would not be needed for that purpose. Ideally, control of HVG and GVH reactions results in mutual graft–host tolerance and initial mixed donor–host hematopoietic chimerism. Although mixed chimerism is likely to correct phenotypic expression of certain genetic diseases, in patients with hematologic malignancies full donor chimerism may be required to control disease through GVT effects. Thus, novel transplantation programs can be designed that are safer than high-dose regimens and have the potential to be administered in the ambulatory care setting rather than on inpatient wards. This chapter discusses the results of clinical studies with reduced-intensity conditioning for hematological malignancies, including the preclinical studies that served as their basis.

Preclinical canine studies

We developed a minimal-intensity transplantation regimen in a canine model that used a small dose of TBI (2 Gy) before and synergistic immunosuppression with mycophenolate mofetil (MMF) and cyclosporine (CSP) after dog leukocyte antigen (DLA)-identical HCT [16]. Most of the dogs so treated showed sustained marrow engraftment. Similar results were obtained when rapamycin was substituted for MMF [17]. In other studies, we substituted 4.5 Gy of irradiation targeted to cervical, thoracic, and upper abdominal lymph nodes for 2 Gy TBI and observed sustained allogeneic engraftment in non-irradiated marrow and lymph node spaces, which suggested that donor T cells were able to create marrow space for the graft to home [18].

Based on the preclinical canine studies, we successfully introduced a minimal-intensity regimen into clinical transplantation, using 2 Gy TBI ± fludarabine before and MMF and a calcineurin inhibitor after HLA-matched transplantation. Clinical results with that approach are discussed below.

Further work in the canine model has been aimed at replacing 2 Gy TBI with radiolabeled monoclonal antibodies (mAbs).

We investigated whether radioimmunotherapy with an α-emitting radionuclide, bismuth-213 (^{213}Bi) or astatine-211 (^{211}At), could be substituted for low-dose TBI. α-Emitters were an attractive alternative to β-emitting radionuclides for targeting hematopoietic cells given that their high energy is deposited over only a few cell diameters (40–70 μm), leading to a high relative biologic effectiveness and sparing surrounding normal tissue. We have previously demonstrated in the canine model that both panhematopoietic anti-CD45 and T-cell-specific anti-T-cell receptor (TCR)αβ mAbs labeled with ^{213}Bi facilitate stable engraftment of DLA-identical marrow in the absence of other conditioning therapy [19–21]. We were not able to translate these studies to the clinic because the parent of ^{213}Bi, actinium-225 (^{225}Ac), was not readily available in quantities sufficient for scale-up to human patient trials, the cost of the isotope was prohibitive, and its half-life (46 minutes) was very short. Accordingly, we investigated the α-emitter ^{211}At, as it was significantly less expensive and its longer half-life of 7.2 hours was particularly attractive as it lends itself to better targeting of hematopoietic cells, including immune cells. Our murine studies found ^{211}At-labeled anti-CD45 mAbs to be more effective than ^{213}Bi in terms of ablating hematopoietic cells and of toxicity [22]. Dose-finding toxicity studies in dogs have been completed and DLA-identical marrow grafts successfully established using ^{211}At-labeled anti-CD45 mAbs [23]. Studies using the ^{211}At-labeled anti-TCRαβ mAbs have been initiated and preliminary results are encouraging. Selectively ablating T cells or ablating all nucleated hematopoietic cells in this way would allow transplantation to be carried out with very low toxicity, making it suitable both for patients with non-malignant and for those with malignant hematologic disorders. Furthermore, mAbs against the panhematopoietic marker CD45 would be useful in patients with major histocompatibility complex (MHC)-non-identical donors where additional host immune cells, such as natural killer (NK) cells, play a major part in graft rejection.

Based on results in both the murine and large animal models, clinical studies with β-emitting radionuclides are ongoing in clinical trials in patients (see Chapter 23). Data from ongoing preclinical studies with α-emitters will allow us to refine future approaches for our patients.

Clinical results

Several groups of investigators have explored the feasibility of reduced-intensity HCT with a variety of regimens to minimize toxicities while exploiting GVT effects. Figure 21.1 outlines the spectrum of commonly used regimens relative to their hypothetical immunosuppressive and myelosuppressive effects. In some cases, drugs were chosen for conditioning that have proven activities against the targeted malignancies for disease control while waiting for GVT effects to occur. With the minimally myelosuppressive regimens, engraftment was ensured by innovative postgrafting immunosuppression that also controlled GVHD, and disease control was more dependent on GVT effects. Other differences among the reduced-intensity regimens included the degrees of marrow aplasia and the tempo of establishing complete donor chimerism. In the reduced-intensity regimens that have more myelosuppressive doses of chemotherapy, recipients uniformly become severely hypoplastic before graft function occurs. Complete donor engraftment occurs rapidly. By contrast, recipients of a less myelosuppressive regimen show only moderate declines of peripheral blood cell counts before recoveries are seen, and all patients are initially mixed donor–host hematopoietic chimeras. In these patients, it may take 6–12 months before donor engraftment is complete.

In order to be able to communicate scientifically within the transplantation community and compare studies using different regimens, there was a need to define what constitutes a reduced-intensity conditioning regimen. At the 2006 Tandem meeting, a workshop was convened by the Center for International Blood and Marrow Transplantation Research (CIBMTR) to help define reduced-intensity conditioning regimens and the consensus included regimens that met the following criteria: (1) a TBI dose of ≤5 Gy if given as a single fraction or 8 Gy if given in a fractionated manner; (2) a BU dose of <9 mg/kg; (3) a melphalan dose of <140 mg/m^2; or (4) a thioTEPA dose of ≤10 mg/kg [24]. Subsequently, there was an attempt to subcategorize regimens further as non-myeloablative regimens, which had the characteristic of causing minimal cytopenias and could also be given without stem-cell support [25]. However, the field has operationally included the "non-myeloablative" regimens with other reduced-intensity regimens as one group.

The comparative benefit of one over another reduced-intensity regimen may depend on the underlying diseases, stage of diseases, and clinical status of the patients. In diseases presumed to be more sensitive to GVT effects, such as chronic myelogenous leukemia, chronic lymphocytic leukemia, myeloproliferative disorders, and low-grade lymphomas (including mantle cell lymphoma), immunosuppressive regimens may be sufficient to ensure engraftment because there is time for GVT effects to become operative. In rapidly progressive diseases or diseases where GVT is less potent or less able to keep ahead of growth of the underlying malignancy, such as high-grade lymphomas, Hodgkin lymphoma, and acute leukemias beyond first remission, a certain amount of cytoreduction may be necessary to minimize residual disease. In this chapter, we discuss strategies of reduced-intensity transplants, with a review of the initial results and current approaches, and with a focus on minimally myelosuppressive TBI-based regimens.

HLA-matched related HCT

Although many studies of reduced-intensity hematopoietic transplants have been performed in elderly and medically infirm patients unable to tolerate a high-dose preparative regimen, some studies have included younger patients who were otherwise eligible for high-dose transplants with standard eligibility criteria. These differences in patient selection generally preclude a meaningful comparison among regimens. Table 21.1 outlines the initial publications regarding reduced conditioning regimens that are currently being utilized.

Initial studies at the M.D. Anderson Cancer Center in Houston, Texas, utilized purine nucleoside analog-based regimens for the treatment of both myeloid and lymphoid malignancies. Giralt et al. [26] combined fludarabine with idarubicin and cytarabine or melphalan, or cladribine and cytarabine before HCT from HLA-identical or single HLA antigen-mismatched sibling donors for treatment of acute myeloid leukemia (AML) or myelodysplastic syndromes. Of 15 patients treated, four failed to engraft, and one treatment-related death occurred before HCT. Khouri et al. [27], also at the M.D. Anderson Cancer Center, treated 15 patients with lymphoid malignancies using a regimen of fludarabine/cyclophosphamide (CY) or fludarabine/cytarabine/cisplatin. Eleven of the 15 patients attained durable engraftment, and eight of the 11 engrafted patients achieved complete remissions. Three non-relapse deaths occurred.

Giralt et al. [28] subsequently reported on a study combining purine analogs (fludarabine or cladribine) with melphalan in patients with hematologic malignancies. It was hypothesized that these drug combinations would have enhanced abilities to achieve remissions given the antitumor effects of high-dose melphalan and the observation that purine analogs have been shown to inhibit DNA repair after alkylator-induced damage. Seventy-eight of 86 patients received fludarabine in combination with high-dose melphalan, and eight received cladribine/melphalan. The day 100 non-relapse mortality (NRM) rate was 37% for the fludarabine/melphalan combination and 88% for the cladribine/melphalan combination. Both regimens were sufficiently immunosuppressive to allow for engraftment of both HLA-matched unrelated and related and one HLA antigen-mismatched related donor grafts. At 1 year, disease-free survival was 57% in patients in first remission or chronic phase and 49% in patients with untreated first relapse or in second or later remission. Responses were seen in patients with refractory disease suggesting the beneficial effect of the cytoreductive conditioning therapy.

Slavin et al. [29] at Hadassah University in Israel used a regimen that consisted of fludarabine, BU (8 mg/kg), and antithymocyte globin (ATG) in a younger group of patients (median age 34 years, range 1–61 years) with both hematologic malignancies and genetic diseases. All patients achieved either partial or complete donor chimerism with this regimen, with four patients developing moderate to severe hepatic sinusoidal obstructive syndrome, suggesting that this regimen was still fairly toxic. The same regimen was used in another group of heavily treated high-risk lymphoma patients with grafts from HLA-matched related and unrelated donors [30]. Again, there was consistent engraftment with disease-free survival of 40% at 37 months. Childs et al. [31] at the National Cancer Institute combined CY and fludarabine to treat patients both with hematologic malignancies and with solid tumors. One of 15 patients rejected the graft, and two patients died of transplant-related causes. The observation was made that full donor T-cell chimerism preceded both acute GVHD and disease regression.

Investigators at the Massachusetts General Hospital in Boston evaluated the use of CY, ATG, and thymic irradiation (among patients without previous mediastinal radiotherapy) in patients given HLA-matched transplants [32]. Eighteen of 20 evaluable patients developed persistent mixed hematopoietic chimerism. Ten of the 20 received prophylactic DLIs to convert mixed to full donor chimerism and to optimize GVL effects. Six of eight patients receiving prophylactic DLIs converted to full donor chimerism. Transplant complications included CY-induced cardiac toxicity. In an attempt to reduce the incidence of GVHD, alemtuzumab (anti-CD52 mAb) was added to fludarabine and melphalan conditioning, in recipients of both HLA-matched sibling and unrelated donor grafts [33]. Forty-two of 43 evaluable patients had sustained engraftment. Eighteen of 31 patients studied were full donor chimeras, while 13 patients were mixed chimeras. The regimen prevented grade III–IV acute GVHD, and only two patients developed grade II GVHD.

While the chemotherapy-based reduced-intensity regimens had significantly fewer toxicities compared with conventional high-dose allogeneic HCT, patients still experienced profound pancytopenias, and most required hospitalizations of durations that were similar to those for high-dose transplants. In order to reduce further the regimen-related toxicities and thereby perform allogeneic HCT in the outpatient setting, the low-dose (2 Gy) TBI conditioning regimen developed in the dog model was evaluated in a

multi-institutional clinical study [34]. TBI of 2 Gy was given as a single fraction on day 0, with postgrafting immunosuppression of CSP from day −1 to day 35, and MMF given twice per day from day 0 to 27. Granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood hematopoietic cells (PBHCs) collected over 2 days from HLA-identical related donors were used as sources of hematopoietic cells. Trial eligibility criteria required patients to be either too old to be eligible for a high-dose HCT or, if younger, to have medical contraindications to high-dose HCT. Overall, the HCT regimen was well tolerated, with the majority of eligible patients having their transplants in the outpatient clinic setting. Most patients did not develop severe neutropenia or thrombocytopenia (Figure 21.2) While all patients had initial donor engraftment, nine (20%) of the first 45 patients experienced graft rejection between 2 and 4 months after transplant, a timing that coincided with discontinuation of the MMF/CSP immunosuppression [34]. Lack of intensive preceding chemotherapy before HCT predicted rejections, and rejecting patients had low-level donor T-cell chimerism on day 28. The rejections were non-fatal, and all patients had autologous reconstitution of peripheral blood counts.

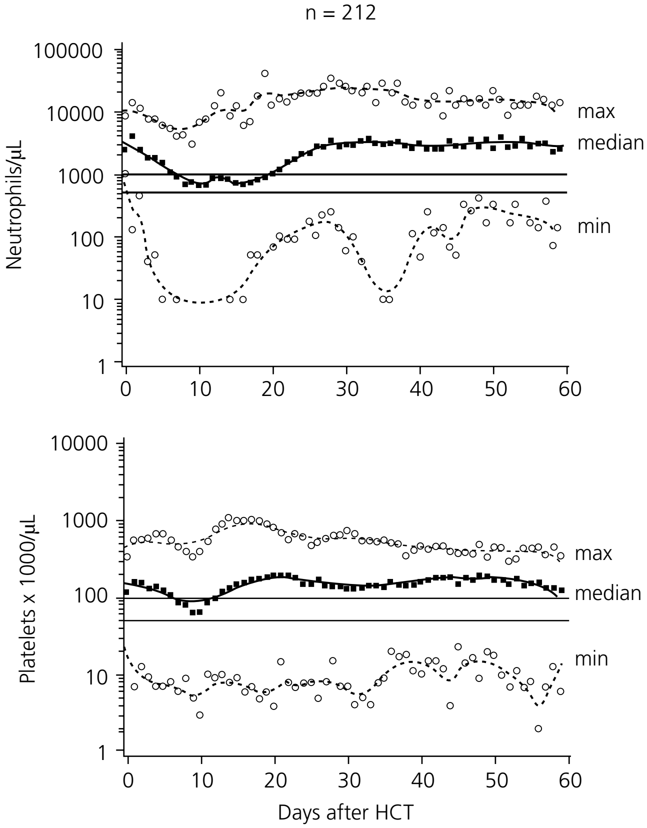

Figure 21.2 Neutrophil and platelet changes among 212 patients given 2 Gy total body irradiation ± fludarabine before and mycophenolate mofetil/cyclosporine after human leukocyte antigen-matched related HCT. Source: Storb 2002 [111]. Reproduced with permission of the American Society of Clinical Oncology.

To prevent graft rejection, the conditioning regimen was modified by adding 30 mg/m^2/day fludarabine on days −4, −3, and −2 to the 2 Gy TBI, with a subsequent reduction of the rejection rate to 3%. In a retrospective analysis of the first 176 patients with hematologic malignancies treated with non-myeloablative HCT from HLA-identical related donors, higher NRM was observed among patients conditioned with 2 Gy TBI and fludarabine (FLU/TBI) (FLU/TBI 31% vs. TBI 14% at 2 years; $p = 0.02$). For this reason, we conducted a prospective phase III randomized trial comparing 2 Gy TBI alone or in combination with fludarabine before transplantation of peripheral blood progenitor cells (PBPCs) from HLA-matched related donors [35]. Eighty-five patients with hematological malignancies were randomized to be conditioned with TBI alone ($n = 44$) or FLU/TBI ($n = 41$). All patients had initial engraftment. Two graft rejections were observed, both in the TBI group. Infection rates, NRM, and GVHD were similar between groups. Three-year overall survival was lower in the TBI group [54% vs. 65%; hazard ratio (HR) 0.57; $p = 0.09$], with higher incidences of relapse/progression (55% vs. 40%; HR 0.55; $p = 0.06$) and relapse-related mortality (37% vs. 28%; HR 0.53; $p = 0.09$), and a lower progression-free survival (36% vs. 53%; HR 0.56; $p = 0.05$). Median donor T-cell chimerism levels were significantly lower in the TBI group at days 28 (61% vs. 90%; $p < 0.0001$) and 84 (68% vs. 92%; $p < 0.0001$), as was NK-cell chimerism on day 28 (75% vs. 96%, $p = 0.0005$). This randomized trial demonstrated the importance of fludarabine in augmenting the graft-versus-tumor effect by ensuring prompt and durable high-level donor engraftment early post-transplant.

The outcomes of different durations of CSP administration were analyzed in 185 patients who received grafts from HLA-matched donors and CSP for 56, 77, or 180 days after HCT in combination with MMF for 28 days. Although the duration of CSP prophylaxis did not significantly influence the overall rate of acute GVHD (grade II–IV), chronic GVHD, or NRM, prolonged administration of CSP (180 days) was associated with a significantly decreased hazard of grade III–IV acute GVHD and an increased likelihood of discontinuing all systemic immunosuppression when compared with the shortest course of CSP (35 days) [36]. Only 3.7% of patients receiving CSP through day 180 developed grade III–IV acute GVHD.

The Stanford group took a different approach to reduce the incidence of GVHD. The reduced-intensity regimen, which was adapted from murine studies that were designed to favor the presence of a high proportion of regulatory NK/T cells [37], consisted of total lymph node irradiation (8–12 Gy total lymphoid irradiation) and ATG (thymoglobulin, 7.5 mg/kg total dose) in combination with MMF and CSP for postgrafting immunosuppression. Of the first 37 patients reported [38], two developed acute GVHD, and nine of 33 evaluable developed chronic GVHD. Further follow-up by this group and others confirmed these low rates of acute GVHD and NRM [39,40].

HLA-mismatched related HCT

The Johns Hopkins group developed a conditioning regimen for HLA-haploidentical related recipients based on a murine model whereby high-dose CY administered after HCT inhibited both graft rejection and GVHD [41]. The regimen for patients consisted of pre-transplant CY 29 mg/kg, fludarabine 150 mg/m^2, and TBI 2 Gy followed by an infusion of marrow and post-transplant CY 50–100 mg/kg, and tacrolimus and MMF (three times per day). A subsequent study expanded on the initial observations [42] in two groups of patients at two centers [Johns Hopkins and Fred Hutchinson Cancer Research Center (Seattle)], which differed in the regimens of post-transplantation immunoprophylaxis [43]. On day 3 (Seattle group) or days 3 and 4 (Johns Hopkins group), 50 mg/kg/day CY was administered. All patients ($n = 68$) received tacrolimus and MMF beginning on the day after the last dose of CY. Of evaluable patients, 13% had graft failure, and 35% and 6% of patients had grade II–IV and III–IV acute GVHD, respectively. The only difference seen between the two groups of patients was that the rate of extensive chronic GVHD in the group that received one dose of post-transplant CY was 25% compared with 5% in the group that received two doses post-transplant ($p = 0.05$). The overall and event-free survivals at 2 years after HCT were 36% and 27%, respectively. The Blood and Marrow Transplant Clinical Trials Network (BMT-CTN) conducted a multicenter phase II trial using the same regimen with two doses of post-transplant CY in patients with leukemia or lymphoma ($n = 50$) [44]. The 1-year probabilities of overall and progression-free survival were 62% and 48%, respectively, after HLA-haploidentical HCT. The 100-day cumulative incidence of grade II–IV acute GVHD was 32%. The 1-year cumulative incidences of NRM and relapse were 7% and 45%, respectively. In parallel, a concurrent BMT-CTN phase II trial using double umbilical cord blood with a similar conditioning regimen gave comparable results [44]. Currently, BMT-CTN is conducting a randomized phase III multicenter trial evaluating the relative risks and benefits of HLA-haploidentical versus double umbilical cord blood HCT using reduced-intensity regimens. Chapters 39 and 44 provide further details regarding cord blood and partially matched related donor HCT, respectively.

HLA-matched and mismatched unrelated HCT

Nagler et al. [45] reported the results of HLA-matched unrelated marrow transplantation following conditioning with fludarabine and BU (8 mg/kg) and ATG. Fifteen of 16 patients achieved 100% donor chimerism, and one patient became a mixed chimera. Seven patients developed grade II–IV acute GVHD, with one patient dying from complications related to acute GVHD. The overall and disease-free survival estimates at 36 months were 75% and 60%, respectively, with this reduced-intensity conditioning regimen in a relatively young population of patients (median age 17 years, range 8–48 years).

Using a similar regimen of fludarabine, BU, and ATG, Bornhauser et al. [46] treated 42 patients with hematologic malignancies with HLA-matched or single HLA antigen-mismatched unrelated grafts. In this older population group (median age 47 years, range 16–65 years), disease-free survival was 64% for patients with lymphoid malignancies, 38% for patients with standard-risk leukemias, and 14% for patients with high-risk diseases. Nine patients (21%) had either primary or secondary graft failures. In patients with stable engraftment, the probability of acute GVHD grade II–IV was 32%.

In a similarly aged group of patients with hematologic malignancies and using a different conditioning regimen consisting of alemtuzumab mAb, fludarabine, and melphalan, Chakraverty et al. described results in 47 patients who received HLA-matched or mismatched unrelated donor transplants [47]. Primary graft failure occurred in two patients, and three patients developed grade III–IV acute GVHD. The overall and progression-free survivals at 1 year were 75.5% and 61.5%, respectively. Bertz et al. reported on 19 patients (aged 60–70 years) with myeloid malignancies who received conditioning with fludarabine, melphalan, and carmustine before HLA-matched related ($n = 7$) or unrelated ($n = 12$) HCT [48]. With a median follow-up of 825 days, the 1-year NRM and survival rates were 22% and 68%, respectively. These results were confirmed in a subsequent update from this group on 34 patients receiving unrelated HCT using this regimen [49]. In summary, fludarabine-based chemotherapy combinations are feasible in older patients or those with comorbidities, and long-term disease control can be achieved with reduced-intensity conditioning in this population of patients.

Using the low-dose TBI (2 Gy) and fludarabine (90 mg/m^2) conditioning regimen, Niederwieser et al. [50] reported on 52 patients with advanced hematologic malignancies given unrelated grafts. It was found that 52% were HLA matched (10/10) level, 29% were one HLA antigen mismatched, and 29% had allele-level mismatches for class I HLA antigens. Durable donor engraftment was attained in 88% of patients and grade II–IV acute GVHD occurred in 63% of patients. In a subsequent study, the same group [51] reported on 89 patients with unrelated donor grafts. Eligibility criteria for this trial included serological matching for HLA-A, -B, and -C, and allele-level matching for HLA-DRB1 and -DQB1. The median patient age was 53 years (range 5–69 years). While the preferred source of stem cells was PBPCs, these were available in only 71 patients, and 18 patients received marrow. Initial donor T-cell engraftment was documented in 87% of patients, with median donor T-cell chimerism on days 28, 56, and 84 being higher in PBPC recipients than marrow recipients ($p = 0.02$, 0.01, and 0.08, respectively). By multivariate analysis, graft rejection was more frequent in marrow recipients ($p = 0.003$) and in patients without preceding chemotherapy ($p = 0.003$). Donor T-cell chimerism values of less than 50% on day 28 were highly associated with eventual graft rejection ($p = 0.001$). Preceding conventional HCT or preceding chemotherapy reduced the risk of rejection, presumably because the prior cytotoxic therapy increased pre-transplant immunosuppression of the host. With a median follow-up of 13 months (range 0.6–28 months), the cumulative probabilities of NRM were 11% at 100 days and 16% at 1 year. The Kaplan–Meier estimates for 1-year survival were 57% versus 33%, and for progression-free survival 44% versus 17% for recipients of PBPCs versus marrow, respectively. A high degree of day 28 CD3 chimerism (>50%) was associated with less relapse ($p = 0.05$). Better progression-free survival was identified in a multivariate analysis in patients with less than 5% blasts in the marrow prior to HCT ($p = 0.0001$) and those who received PBPCs as a hematopoietic stem cell source ($p = 0.006$).

The study suggested that PBPCs were the preferred source of grafted hematopoietic cells in unrelated transplantation with a fludarabine/2 Gy TBI conditioning regimen. Given the importance of postgrafting immunosuppression both to facilitate engraftment and to reduce the risk of GVHD, our attention was drawn to another finding of the study, the short (3.5-hour) serum half-life of the active metabolite of MMF, mycophenolic acid (MPA). This finding resulted in a modification of the post-transplant immunosuppression: an increase in the dosing of MMF to three times daily in the hope of minimizing the risk of late graft rejections. Among 103 patients so treated, graft rejections occurred in 5%, whereas acute GVHD remained at 53%, with 2-year NRM and overall and progression-free survival of 19%, 58%, and 49%, respectively [52]. Because three times daily compared with twice-daily MMF diminished the incidence of graft rejection, MMF should be administered three times per day in unrelated recipients receiving this regimen.

We recently published results of a three-arm, randomized, phase II study of GVHD prevention involving 208 unrelated recipients. Patients in all arms were given MMF and tacrolimus and in arm 3 sirolimus was added. There was a significantly lower incidence of grade II–IV acute GVHD ($p = 0.04$) in the MMF/tacrolimus/sirolimus arm (47%) than the reference arm (64%) consisting of tacrolimus and MMF; however, this was not significantly lower than the historical experience of 52% with MMF/CSP ($p = 0.12$) [53]. A second important finding was that MMF/tacrolimus (without added sirolimus) was no better than the historically used MMF/CSP at preventing acute GVHD among unrelated recipients. The findings from this study are the basis for the currently ongoing randomized two-arm, phase III study whereby both arms use CSP until day 96, with taper to day 150. Arm 1 is the "reference arm" in which MMF is given three times daily until day 30, then twice daily until day 150 with a taper through day 180 in an attempt to avoid late-onset acute GVHD. In arm 2, sirolimus is given until day 150 with a taper though day 180. In arm 2, in addition to CSP and sirolimus, MMF is given through day 40.

A recent publication summarized outcomes in 1092 HLA-matched related ($n = 611$) and unrelated ($n = 481$) recipients with hematologic malignancies given fludarabine and low-dose TBI before and MMF and a calcineurin inhibitor after HCT [54]. Whereas chronic GVHD and GVT effects were comparable after related and unrelated HCT, unrelated recipients experienced more acute GVHD and higher NRM (HR 1.41; $p = 0.002$).

We extended non-myeloablative HCT to patients with HLA class I mismatched donors with mismatches at the antigen level [55]. To prevent graft rejection and optimize GVHD prophylaxis, patients received CSP and MMF longer than HLA-matched recipients. Only 2 of 60 patients rejected their grafts. However, rates of acute GVHD (grade II–IV, 69%; grade III–IV, 26%) were high, with a 2-year NRM of 47%. Sirolimus has been effective as GVHD prophylaxis after HLA-matched and mismatched unrelated HCT [56–58]. Based on the observed possible superior GVHD control with a combination of sirolimus, MMF, and tacrolimus in HLA-matched unrelated donor HCT compared with MMF and tacrolimus alone, a trial using CSP, MMF, and sirolimus has been initiated.

We evaluated the pharmacodynamic relationships between MPA, the active metabolite of MMF, and outcomes in 308 patients conditioned with fludarabine/TBI who received grafts from HLA-matched related (n = 132) or unrelated (n = 176) donors [59]. All patients received post-grafting immunosuppression with MMF and a calcineurin inhibitor. Rejection occurred in nine patients, eight of whom had a total MPA concentration at steady state (C_{ss}) of less than 3 μg/mL. In patients receiving an unrelated donor graft, a total MPA of C_{ss} less than 2.97 μg/mL was associated with increased grade III–IV acute GVHD ($p = 0.05$) and increased NRM ($p = 0.007$). MPA C_{ss} was not associated with clinical outcomes in patients receiving a related donor graft. Future prospective studies are warranted to confirm whether higher initial oral MMF doses and subsequent targeting of total MPA C_{ss} to greater than 2.96 μg/mL could lower grade III–IV acute GVHD and NRM in patients receiving an unrelated donor graft.

Chimerism and engraftment kinetics

Donor chimerism after allogeneic HCT can be evaluated by several means. Currently, fluorescent in situ hybridization of sex chromosomes and amplified fragment length polymorphism analysis are the most commonly used methods (reviewed in [60] and see Chapter 24). Amplified fragment length polymorphism-based techniques utilize the polymerase chain reaction (PCR) for analysis of polymorphic DNA sequences such as variable number of tandem repeats or short tandem repeats. Additionally, real-time PCR of single nucleotide polymorphisms is being evaluated for this purpose.

Reduced-intensity conditioning usually leads to an initial state of mixed chimerism [31,61–63], although some patients given grafts after more myelosuppressive regimens achieve full donor chimerism in cellular subsets as early as day 14 after HCT [64]. Childs et al. [31] evaluated the kinetics of engraftment after conditioning with fludarabine (125 mg/m^2) and CY (120 mg/kg). Most frequently after that regimen, full donor chimerism was achieved earlier in peripheral blood T cells than in myeloid cells. The NK-cell chimerism correlated with the T-cell chimerism, whereas the B-cell chimerism was distinct from the T-cell and myeloid lineages. Bornhauser et al. observed that patients with NK chimerism below 75% in the first month after unrelated donor HCT had a higher risk of graft failure after conditioning with fludarabine 150 mg/m^2, BU 6.6 mg/kg intravenously, and ATG [46]. The kinetics of chimerism were also evaluated in patients who received conditioning with 2 Gy TBI with or without fludarabine (90 mg/m^2) [63]. Most patients remained mixed donor–host chimeras for up to 3–6 months after HCT. Patients given preceding chemotherapy or peripheral blood stem-cell grafts had the highest degrees of donor chimerism. High levels of donor T- or NK-cell chimerism (>50%) 28 days after HCT have each been associated with a reduced risk of graft rejection [34,63]. There was also an association with higher donor T-cell chimerism and an increased risk of grade II–IV acute GVHD [63]. A subsequent study in 282 patients modeling chimerism levels as a continuous linear variable confirmed that high early donor T-cell chimerism was associated with acute GVHD ($p = 0.01$), whereas high donor NK-cell chimerism had no association with GVHD ($p = 0.38$) [65]. Whereas high donor T-cell chimerism levels only trended to a lower risk of relapse ($p = 0.10$), high donor NK-cell chimerism levels were significantly associated with lower relapse risk ($p = 0.0009$).

An association between the kinetics of engraftment and GHVD was observed by Childs et al. [31]. The achievement of full donor T-cell chimerism preceded the development of grade II–IV GVHD in patients who received conditioning with fludarabine and CY. Studies by Mattsson et al. [66], by contrast, found that 82% of patients had mixed donor–host T-cell chimerism at the time of the development of acute GVHD. This is similar to the results observed after conditioning with TBI with or without fludarabine, in which 83% of the patients were mixed donor–host T-cell chimeras at the time of the development of GVHD [63]. However, when chimerism was analyzed as a continuous linear variable, patients with higher levels of donor T-cell chimerism on day 28 after HCT were at higher risk for grade II–IV acute GVHD [34,51,63], with a corresponding reduced risk of relapse in those patients who achieved full donor T-cell chimerism [63].

GVHD and GVT effects

Reconstitution of donor-derived immunity after reduced-intensity conditioning differed from what occurred after high-dose conditioning. First, as mentioned above, there was an initial state of mixed donor–host chimerism in the recipients of reduced-intensity conditioning that changed the balance of both GVH and HVG tolerance, which may affect the onset of GVHD. Second, high-dose conditioning regimens may contribute to the pathophysiology of GVHD via tissue damage causing the release of cytokines, the so-called “cytokine storm” [67]. However, the number of host-derived antigen-presenting cells may be higher after reduced-intensity conditioning, thus contributing to acute GVHD given their putative role in the initiation of GVHD [68].

Historically, the occurrence of GVHD was associated with GVT effects in patients receiving high-dose conditioning regimens [1,2]. Several retrospective analyses have been carried out to evaluate the impact of GVHD and GVT on outcomes after reduced-intensity conditioning regimens since the regimens themselves have less of a role in disease control. Most have shown lower incidences of acute and similar or lower incidence of chronic GVHD in recipients of reduced intensity as compared with high-dose HCT [69–72]. One age-matched retrospective analysis was carried out comparing the incidence of GVHD in recipients of reduced-intensity versus high-dose conditioning. The cumulative incidence of grade II–IV acute GVHD was lower in reduced-intensity HCT (64% versus 85%; $p = 0.001$), resulting in the use of less systemic immunosuppression during the first 3 months after transplant [69]. There was no difference in the cumulative incidence of chronic GVHD requiring treatment. Of note, reduced-intensity HCT was associated with a syndrome of acute GVHD occurring beyond day 100 in a subset of the related recipients, and this should be taken into consideration in the design of prospective studies comparing reduced-intensity and high-dose HCT. Martino et al. demonstrated a reduced risk of relapse in patients with AML and myelodysplastic syndrome who experienced acute and/or chronic GVHD compared with those who did not [73]. Kroger et al. found that while there was no impact of acute GVHD on the risk of relapse in patients with multiple myeloma, there was a significantly lower risk of relapse in patients who had chronic GVHD [74]. These outcomes were also observed in an

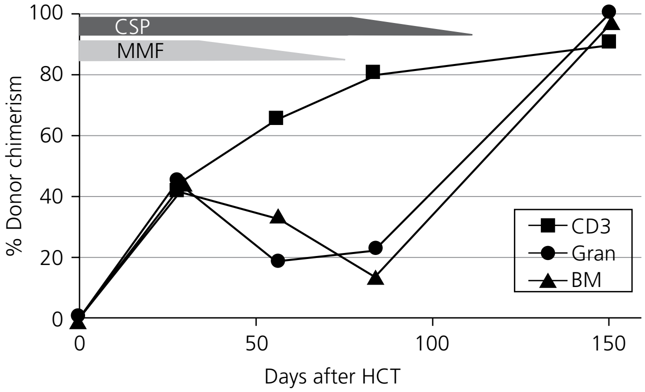

Figure 21.3 Donor chimerism (fluorescence in situ hybridization) in a patient with Philadelphia chromosome-negative myeloproliferative disorder after unrelated HCT. BM, bone marrow; CSP, cyclosporine; Gran, granulocytes; MMF, mycophenolate mofetil.

analysis of multiple myeloma patients by Crawley et al. for the European Group for Blood and Marrow Transplantation [75]. Blaise et al. performed a landmark analysis starting on day 100 in patients with AML and observed a lower risk of relapse and higher leukemia-free survival in the patients who developed chronic GVHD [76].

Figure 21.3 illustrates the donor chimerism changes in a 65-year-old patient with Philadelphia chromosome-negative myeloproliferative disorder whose disease was characterized by high white blood cell counts, very high platelet counts (>10^6/mL), and high basophil counts. The patient's T-cell chimerism increased to 80% by day 84, whereas the marrow and granulocyte donor chimerism declined from 40–45% on day 28 to 10% in the marrow on day 84. The patient's platelet and basophil counts increased to 900,000 and 1500/mL, respectively, consistent with disease progression after an initial response. CSP was rapidly tapered to induce a GVT response. The marrow and granulocyte donor chimerism rose to nearly 100% by day 150, and both basophilia and thrombocytosis resolved. The patient also developed mild signs of chronic GVHD that responded to CSP. The patient is surviving over 13 years after HCT, with complete donor engraftment and no evidence of recurrent myeloproliferative disorder. This clinical case illustrates the relationship between postgrafting immunosuppression, GVHD, and GVT effects. It also emphasizes the importance of lineage-specific chimerism evaluations in monitoring patients.

Reduced-intensity allogeneic HCT relies on GVT effects for the eradication of malignancy. An analysis was carried out in recipients of related or unrelated grafts who had received conditioning with 2 Gy TBI with or without fludarabine to obtain an estimate of relapse risk according to disease characteristics [77]. Relapse rates per patient-year at risk for the first 2 years after HCT were calculated for 29 different diagnosis and disease stages. Using this algorithm, patients were grouped into low, standard, or high relapse risk for each disease and disease stage. The lowest risk group included patients with B-cell malignancies including chronic lymphocytic leukemia and non-Hodgkin lymphoma (NHL) at any stage except aggressive NHL not in complete remission (CR). Patients with advanced myeloid and lymphoid malignancies had the highest relapse rates after reduced-intensity HCT.

The prognostic relevance of GVHD was recently evaluated in 1092 patients with advanced hematologic malignancies who had HCT from HLA-matched related ($n = 611$) or unrelated ($n = 481$) donors after conditioning with low-dose TBI ± fludarabine followed by immunosuppression with MMF and a calcineurin inhibitor [54]. The regimen avoids serious toxicities and has minimal cytotoxic antitumor effects, allowing the evaluation of both GVHD and GVT. The median patient age was 56 years (range 7–75 years) and the median follow-up time was 5 years. The cumulative incidences of grade II–IV acute GVHD and chronic GVHD were 43% and 49%, respectively, with related donors, and 59% and 50%, respectively, with unrelated donors. Grade IV acute GVHD was seen in 3% of patients. The 5-year NRM and relapse mortality were 24% and 34.5%, respectively. Respective 5-year event rates among related compared with unrelated recipients were 20.5% and 28.4% for NRM and 34.5% and 34.5% for relapse mortality. Most NRM was in patients with a history of GVHD and NRM increased in direct relation to increasing grade of acute GVHD. Serious pretransplant comorbidities and grafts from unrelated donors were the most significant factors associated with GVHD-associated NRM. There was an association of acute GVHD with NRM but not with GVT effects. Although chronic GVHD was associated with significantly lower relapse or progression rates, the high associated NRM offset this benefit. The 5-year survival ranged from 25% to 60% and was influenced by disease risk, GVHD, and comorbid conditions (Figure 21.4). Relapse rates were highest during the first 2 years after HCT, whereas rates during years 3–5 were low (Table 21.2) Comparable GVT effects among related and unrelated recipients were also observed in a CIBMTR report following high-dose allogenic HCT [78].

In a recent study of 459 patients with hematologic malignancies given either a related or unrelated HCT after minimal intensity conditioning, we explored whether peri-transplant neutrophil or lymphocyte levels predicted GVHD or GVT effects [79]. We made two key findings. First, low neutrophil nadirs in the first 3 weeks after HCT predicted increased risks of acute GVHD and NRM but had no association with relapse risk. Second, high lymphocyte counts immediately before HCT predicted reduced risks of relapse and overall mortality, without association with the risks of GVHD or NRM, suggesting that the immunologic mechanisms underlying acute GVHD might differ from those that initiate GVT effects.

Major efforts should therefore be directed to more effective GVHD prophylactic regimens in addition to strategies that control the progression of malignant disease early after transplant. Such strategies include the use of tyrosine kinase inhibitors in patients with bcr/abl-positive disease which has been shown to be effective for Philadelphia-positive acute lymphoblastic leukemia (ALL) [80]. Other newer strategies include use of peri-transplant idelalisib for chronic lymphocytic leukemia, quizartinib for AML, or brentuximab vedotin for Hodgkin lymphoma. Lastly, in order to improve patient outcomes in the high-risk group, the option of allografting should be considered earlier in the disease course when the tumor burden is lower.

Toxicities

In a retrospective cohort study, recipients of reduced-intensity conditioning ($n = 503$) had significantly reduced transfusion requirements compared with high-dose HCT recipients ($n = 1353$), with only 36% of the patients requiring platelet transfusions and 75% requiring red blood cell (RBC) transfusions compared with 99% and 96%, respectively, of high-dose HCT recipients ($p < 0.0001$) [81]. Recipients of reduced-intensity HCT who did require transfusions used significantly fewer units of platelets and RBCs ($p < 0.0001$ for both). Platelet and RBC transfusions were less frequent

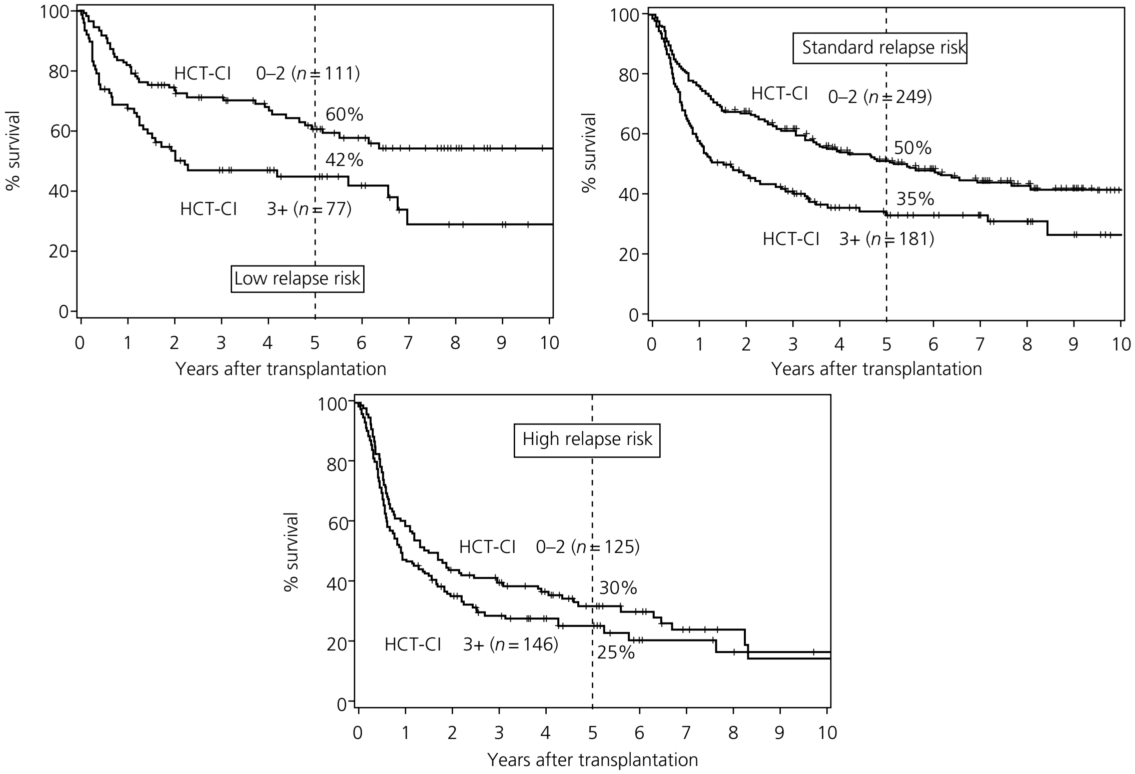

Figure 21.4 Five-year survival (%) of patients with advanced hematologic malignancies who were conditioned with fludarabine and low-dose TBI and given postgrafting MMF and calcineurin inhibitor. Survivals are shown depending on relapse risk and hematopoietic comorbidity index scores (HCT-CI).

Table 21.2 Relapse rates per patient-year among 1,092 patients

Diagnosis (No.; % related/ unrelated)	**Stage**	***n***	**Rate**

among related compared with unrelated recipients (p = 0.0001 for both). ABO-matched recipients required fewer RBC transfusions than major/directionally ABO-mismatched recipients (p = 0.006). ABO incompatibility did not affect other HCT outcomes including GVHD, rejection, relapse, NRM, or survival. Recipients of reduced-intensity conditioning had shorter periods of neutropenia than recipients of high-dose conditioning ($p < 0.0001$), and this was associated with fewer episodes of bacteremia during the first 30 days (p = 0.01) [82]. Similarly, there was a trend to less cytomegalovirus antigenemia, viremia, and disease in reduced-intensity HCT recipients compared with recipients of high-dose conditioning, with a significant reduction when more serious manifestations (cytomegalovirus viremia and disease) were combined during the first 100 days (p = 0.01) [83]. A more recent transition to a preemptive therapy strategy based on CMV viral load and host risk factors successfully prevented CMV disease without increasing the proportion of patients receiving preemptive therapy and attributable toxicity [84]. The incidence of idiopathic pneumonia syndrome was significantly lower following reduced-intensity conditioning compared with high-dose conditioning regimens (2.2% versus 8.4%; p = 0.003) [85].

Liver injury is a frequent, serious complication of high-dose preparative regimens. The frequency and severity of hepatic injury after reduced-intensity conditioning were evaluated in 193 consecutive patients [86]. No patients developed sinusoidal obstructive syndrome. About 26% of patients developed hyperbilirubinemia of 4 mg/dL or more, most commonly resulting from cholestasis due to GVHD or sepsis. Overall survival was superior for patients who had maximum bilirubin in the normal or minimally elevated (1.3–3.9 mg/dL) ranges compared with those in the elevated (≥4 mg/dL) ranges.

Incidences of acute renal failure (ARF) among recipients of high-dose and reduced-intensity conditioning were compared [87]. Severity of ARF was classified into four grades based on serum creatinine increases in the first 100 days after HCT. Recipients of reduced-intensity conditioning were significantly older and had greater pre-transplant comorbidities. Despite this, high-dose patients had greater incidences of severe ARF (73% versus 47%; $p < 0.001$) and dialysis (12% versus 3%; $p < 0.001$) compared with those receiving reduced-intensity regimens. NRM was also greater in the high-dose group at 100 days and 1 year. The incidences of chronic kidney disease after reduced-intensity HCT were analyzed in 122 patients from three centers [88]. Multivariate analysis revealed that ARF in the first 100 days was associated with chronic kidney disease. Previous autologous HCT, long-term calcineurin use, and chronic GVHD were independently associated with chronic kidney disease. Future research should focus on preventing ARF and decreasing the use of calcineurin inhibitors.

Outcomes among 1148 patients transplanted between 2003 and 2007 were compared with those among 1418 patients transplanted between 1993 and 1997 at a single center [89]. On average, the patients in the more recent cohort were older, had more comorbidities, and had more advanced disease then the older cohort. There were significant decreases in overall mortality, including mortality not preceded by relapse. This was primarily related to reduced organ damage, infection, and severe acute GVHD, which in part reflected the current use of reduced-intensity conditioning for allogeneic HCT. Improvements in overall mortality were seen in recipients of both reduced-intensity and high-dose conditioning, highlighting progress in supportive care that impacted outcomes for all patients.

Comparing morbidity and mortality: influence of pre-transplant comorbidities

Comorbidities, defined as any additional clinical entity in a patient with an index disease, affect therapeutic plans and outcomes after treatment for the index disease. With the advent of reduced-intensity conditioning regimens, HCT is being carried out in older patients and those with considerable comorbidities. Objective measures of patients' underlying health are required in order to study and disseminate transplantation approaches in an older and medically less fit population.

Data have suggested that comorbidity indices are useful tools in predicting outcomes that can be used in the design of inclusion/exclusion criteria for clinical trials. One of the indices used was the Charlson Comorbidity Index (CCI), which was originally developed in a cohort of patients at a general medical center [90]. The CCI was successfully applied to patients with hematologic malignancies after HCT following both high-dose and reduced-intensity conditioning regimens in related [91] and unrelated [92] recipients, although it had limitations. A new HCT-Comorbidity Index (HCT-CI) was developed to incorporate HCT-related comorbidities and define better previously defined comorbidities by incorporating pre-transplant laboratory parameters. The HCT-CI had better survival prediction than the CCI [92].

This tool has been validated in patients with myelodysplasia or AML, where similar outcomes have been found after high-dose and reduced-intensity conditioning after stratification of patients into low- and high-risk disease categories and low and high HCT-CI scores [93]. This suggested that patients with low HCT-CI scores could be candidates for randomized trials comparing conditioning intensity and a prospective multi-institutional phase III study is currently ongoing with the BMT-CTN in patients with myelodysplasia and AML. A prospective multi-institutional observational study was initiated at the CIBMTR to collect comorbidities from all transplant centers. The HCT-CI was a valid tool to discriminate relative risks for NRM and survival after HCT across different institutions, different conditioning intensities, and different diagnoses [94].

Long-term outcomes were investigated among patients 60 years of age and older after conditioning with low-dose TBI and fludarabine on prospective trials followed by related ($n = 184$) or unrelated ($n = 188$) donor HCT [95]. The 5-year cumulative incidence of NRM was 27% and was not different among the different age groups. Increasing age was not associated with increases in acute or chronic GVHD or other organ toxicities. Increasing HCT-CI scores were associated with worse outcomes, as were standard or high relapse risk. The 5-year overall and progression free-survivals were 35% and 32%, respectively.

Consolidative reduced-intensity allografts following planned autografts

In patients with aggressive malignancies, the GVT effect following a reduced-intensity allograft may not be sufficiently fast enough to eradicate large-volume disease. Carella et al. adopted the strategy of using debulking autologous HCT followed by reduced-intensity allogeneic HCT in patients with refractory Hodgkin and non-Hodgkin lymphomas [96] and Kroger et al. reported a similar approach in multiple myeloma [97]. Maloney et al. also published results for patients with multiple myeloma who were given a cytoreductive autograft with melphalan conditioning (200 mg/m^2) followed by an allograft from an HLA-identical sibling after conditioning with 2 Gy TBI [98]. With a median follow-up of 550 days after allograft in surviving patients, the overall survival rate was 78%. The overall disease response rate was 83%, with 57% of patients achieving complete remission and 26% partial remission. Based on this study, a phase III trial comparing tandem autologous transplantation with tandem autologous/allogeneic (auto/allo) transplantation was carried out by the BMT-CTN. A total of 710 patients were enrolled and the median follow-up was 40 months. In the standard risk patients, the 3-year progression-free survival was 43% in the auto/allo group and 46% in the auto/auto group, and overall survival also did not differ [99]. Disease relapse remains the major problem in both groups, suggesting that post-HCT maintenance therapy is needed.

Another trial based on this approach was reported by Bruno et al., who compared allografting with autografting for newly diagnosed multiple myeloma [100]. Patients ($n = 162$) were enrolled at the time of diagnosis and treated with vincristine, doxorubicin, and dexamethasone followed by melphalan and autologous PBPC infusion. Patients with an HLA-identical sibling then received 2 Gy TBI and PBPCs from the sibling donor, whereas those without an HLA-identical sibling received a second autograft. In an updated report with a median follow-up of 7.3 years (range 5.4–10.4 years), the median survival was not reached in the 80 patients with an HLA-identical sibling versus 4.25 years for 82 patients without ($p = 0.001$) [101]. Among patients who completed their treatment protocols, the median overall survival was not reached ($p = 0.02$) and the event-free survival was 3.25 years ($p = 0.02$) in the auto/allo group ($n = 58$), whereas the overall survival was 5.3 years and event-free survival was 2.75 years in the tandem autologous group ($n = 46$).

An update at a median follow-up of 8 years (range 3.9–10.6 years) of the European Group for Blood and Marrow Transplantation Non-Myeloablative Allogeneic Stem Cell Transplantation in

Multiple Myeloma (NMAM) 2000 study that prospectively compared tandem auto/allo with autologous HCT alone. Patients up to age 69 years were enrolled ($n = 357$). Patients with an HLA-identical sibling were allocated to auto/allo ($n = 108$) and those without to autologous (auto) HCT alone ($n = 249$). The progression-free survival and overall survival at 8 years were 22% and 49% versus 12% and 36% in the auto/allo versus auto group, respectively [102]. The authors concluded that long-term outcomes were better with auto/allo than auto and that a follow-up longer than 5 years is necessary for correct interpretation of the additive value of an allogenic HCT.

Reduced-intensity allografting after failed high-dose transplants

Use of conventional high-dose conditioning for allografts following failed autologous or allogeneic HCT has resulted in poor outcomes in adult patients, primarily related to early fatal regimen-related toxicities [103]. A number of investigators have therefore evaluated reduced-intensity regimens to condition patients for second HCT. Investigators in Jerusalem conditioned patients with fludarabine, BU, and ATG, with CSP as GVHD prophylaxis [104]. Among 12 relatively young patients transplanted (median age 33 years, range 8–63 years), one non-relapse death occurred and six patients were disease-free with a median follow-up of 23 months. Actuarial overall and disease-free survivals were 56% and 50%, respectively, at 34 months. Investigators at Massachusetts General Hospital described their results with 13 patients (median age 38 years) who relapsed following autologous HCT and received HLA-matched related donor allografts following conditioning with CY and ATG with or without thymic irradiation [105]. DLI was administered at 5–6 weeks post-transplant to facilitate full donor chimerism. One non-relapse death occurred, and 2-year estimates of overall and disease-free survivals were 45% and 38%, respectively.

Investigators at the City of Hope National Medical Center have described their results for 28 patients who failed previous autologous transplants or developed myelodysplastic syndrome after autografts [106]. The median interval from the failed autologous HCT and allogeneic HCT was 15 months. The median age of the patients was 47 years, and patients were treated with either fludarabine plus melphalan ($n = 24$) or fludarabine plus 2 Gy TBI ($n = 4$). Patients received HCT from either HLA-matched related ($n = 14$) or unrelated ($n = 14$) donors. The day 100 mortality and NRM were 25% and 21%, respectively. With a median follow-up of 2 years in surviving patients, the 2-year probabilities of overall survival, event-free survival, and relapse rate were 56.5%, 41%, and 41.9%, respectively.

The Seattle Consortium reported on 147 patients (median age 46 years, range 9–73 years) who failed conventional autologous ($n = 135$), allogeneic ($n = 10$) or syngeneic ($n = 2$) HCT and subsequently received HLA-matched related ($n = 62$) or unrelated ($n = 85$) grafts after 2 Gy TBI-based regimen (with or without fludarabine) [107]. The 3-year NRM was 32% in related recipients and 28% in unrelated recipients with a median follow-up of 2.2 years (range 0.23–5.3 years). The Kaplan–Meier estimates of relapse and overall survival were 48% and 32%, respectively, for related recipients, and 44% and 44%, respectively, in unrelated recipients. The best outcomes were observed in patients with non-Hodgkin lymphoma, whereas patients with multiple myeloma and Hodgkin lymphoma had the poorest outcomes due to high incidences of relapse and progression. A lower risk of relapse or progression was seen in patients in partial or complete remission at the time of HCT and in patients who developed chronic GVHD. Factors associated with better overall survival were the partial or complete remission of the underlying disease and lack of comorbidity at the time of HCT. Hence allogeneic GVT effects can be used with some success in patients for whom other treatment options have been exhausted, including high-dose therapy with hematopoietic cell rescue (either autologous or allogeneic). Outcomes using related or unrelated donors were comparable.

Thirty-eight patients underwent salvage reduced-intensity HCT after rejection (in the absence of relapse) of the first allograft [108]. Conditioning included 3–4 Gy TBI in addition to fludarabine. In 14 cases the original donor was used and in 24 cases different donors were used. Sustained engraftment was achieved in 87% of patients with rejections in five patients, of whom four had myelofibrosis. The 2-year NRM and overall survival were 24% and 49%, respectively. These data indicate that graft rejection can be overcome by salvage HCT using fludarabine and low-dose TBI.

The role of second allogeneic HCT was investigated in 90 consecutive patients with hematologic malignancies (median age 34 years, range 3–68 years) who relapsed after first allogeneic HCT and underwent second or subsequent allografts [109]. The majority of patients (89%) had relapsed following a high-dose conditioning regimen. In 15 cases the original donors were used for second HCT, and in 75 cases different donors were identified. Conditioning for second HCT included low-dose TBI (2–4 Gy) with or without fludarabine, with or without CY ($n = 49$), treosulfan, and fludarabine-containing regimens with or without low-dose (2 Gy) TBI ($n = 17$), high-dose TBI ($n = 16$), or BU ($n = 8$) based regimens. With a median follow-up of 3.2 years (range 0.6–12.8 years) among surviving patients, the 2-year Kaplan–Meier overall survival, relapse rate, and NRM estimates were 36%, 44%, and 27%, respectively. Relapse was the leading cause of treatment failure. Patients with early relapse after their first allogeneic HCT (within 6 months vs. 6–12 months vs. more than 12 months) had significantly higher 2-year relapse rates after second transplants (64%, 44%, and 31%, respectively; $p = 0.01$). This translated into overall survival differences with borderline statistical significance (21%, 24%, and 51%, respectively, $p = 0.08$). Patient age, donor type, same versus different donors for second HCT, conditioning intensity, and HCT comorbidity scores did not appear to affect outcomes in univariate analyses in this group of patients. Based on this retrospective analysis, second allogeneic HCT should be considered for post-transplant relapse, especially in patients who relapse more than 12 months after their first allografts.

Conclusion

The use of reduced-intensity or minimally myelosuppressive preparative regimens has resulted in durable allogeneic hematopoietic engraftment and the development of GVT effects in the setting of underlying malignant diseases. The regimens have been relatively non-toxic in older patients and have been successfully applied to younger patients with comorbid conditions that had excluded them from high-dose HCT. The optimal regimen may ultimately be defined by the nature of the diseases being treated. In aggressive lymphomas, acute leukemias not in remission, and other fast-growing malignancies, cytoreduction by either preceding chemotherapy with or without autologous stem-cell rescue, or the use of a reduced-intensity regimen with disease-specific chemotherapy, may be necessary to allow time for adequate GVT responses to develop. For low-grade or mantle cells lymphomas, acute leukemias in first complete remission, chronic leukemias, and other more indolent diseases, minimal reduced-intensity regimens may be sufficient for successful outcomes by allowing the donor T cells to generate sufficient GVT responses and eradicate the underlying malignancies, but here too, prevention of relapse using disease-specific approaches post-transplant is being studied.

Other current issues include minimizing GVHD, which would avoid prolonged immunosuppression, thereby reducing the risk for infections that otherwise contribute significantly to NRM in all regimens. Additionally, prolonged immunosuppression may blunt optimal GVT effects. Ultimately, reduced-intensity HCT might be used to establish mixed donor–host chimerism that can serve as a platform for adoptive immunotherapy with the infusion of tumor-specific cytotoxic T cells that would exert GVT effects without causing GVHD.

In the future, reduced-intensity transplants may become the procedure of choice also for younger patients with either malignant or non-malignant diseases. Towards that end, BMT-CTN 0901 is carrying out a randomized, phase III study of allogeneic HCT comparing regimen intensity in patients with myelodysplastic syndrome or AML. Additional phase III studies are needed to determine both immediate- and long-term outcomes in different disease categories and age groups.

CHAPTER 22

Radiotherapeutic Principles of Hematopoietic Cell Transplantation

Jeffrey Y.C. Wong and Timothy Schultheiss
City of Hope Cancer Center, Duarte, CA, USA

Introduction

Since the initial pioneering efforts of Thomas and colleagues [1], radiation therapy continues to be an important part of conditioning regimens in patients undergoing hematopoietic cell transplantation (HCT). Irradiation is used primarily as a form of systemic therapy utilizing high-energy photons and large fields to deliver total body irradiation (TBI). In addition, total lymphoid irradiation (TLI) and locoregional irradiation directed to areas of higher tumor burden have also been combined in HCT conditioning regimens.

A primary role of TBI is the eradication of malignant cells. In patients undergoing allogeneic HCT, TBI also provides a powerful means of immunosuppression to prevent rejection of donor hematopoietic cells. TBI is often combined with chemotherapy in conditioning regimens and offers distinct advantages over chemotherapy. Unlike chemotherapy, delivery of radiation therapy to the tumor site is not dependent on blood supply or influenced by inter-patient variability of drug absorption, metabolism, biodistribution, or clearance kinetics. Radiation therapy can reach potential sanctuary sites, such as the testes and brain. Chemotherapy-resistant clones that develop may still be sensitive to irradiation.

Unlike in chemotherapy, the radiation dose can be preferentially distributed to areas of greatest tumor burden and restricted to critical normal organs. Past efforts utilized shielding to reduce the dose to critical organs such as the lung, kidney, or liver, or delivered additional locoregional radiation therapy as boost treatment to areas of greatest tumor burden. Recent advances in radiation therapy delivery systems now allow for new and novel opportunities to target radiotherapy selectively in the setting of HCT. Biologically targeted systemic radiotherapy, using radiolabeled antibodies or bone-seeking radiopharmaceuticals such as ^{166}Ho-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetramethylenephosphonic acid (DOTMP), have been evaluated as part of conditioning regimens in clinical trials. Advances in the delivery of external beam radiotherapy using intensity-modulated radiation therapy (IMRT) coupled with image-guided radiation therapy (IGRT) now allow the radiation oncologist to "sculpt" dose distribution to the unique shape of each patient's tumor. These advances are being translated to large-field applications and are being actively investigated as a means of image-guided targeted TBI or total marrow irradiation (TMI) [2–7].

This chapter provides an overview of the principles and concepts in radiobiology and radiation physics that are important in optimizing TBI. An understanding of these principles is essential to minimize toxicities, maximize tumor cell eradication, and optimize the therapeutic ratio of this important treatment modality. Dose to tumor, dose to organs, volume of critical organ receiving a given dose, fraction size, number of fractions, time between fractions, dose rate, beam energy, uniformity of dose distribution within the target region, and reproducibility of patient alignment and set-up are all critical factors to consider in optimizing outcomes. The clinical results and normal tissue toxicities of TBI are reviewed and provide examples of how the rational application of radiobiology and radiation physics has led to improved outcomes. Finally, the rationale, methods, and clinical results of the new, targeted TBI strategies utilizing IGRT and IMRT technologies are described.

Radiobiology principles

It is now clear that fractionated TBI is superior to and associated with less toxicity than single-fraction TBI [8,9]. The issue of dose rate has not really been addressed systematically. In examining dose-rate effects, most studies have ignored the important influence of fractionation on the dose-rate effect and have also ignored the fact that dose-rate effects will be different for each different cell type irradiated. Hence the fundamental radiobiologic questions that remain in TBI are how should the treatment be fractionated and, given this fractionation, is there a dose-rate effect in the cell types of interest that is significant enough to be worth pursuing?

The fundamental response to radiation is generally described by a cell survival function. This function gives the probability, S, that a given cell will survive a dose, d, of radiation. Of course, S depends upon the type of cell, its phase in the cell cycle, and the conditions under which it is irradiated, including the type of radiation. There are many mathematical models that describe the dependence of S on d [10]. If cells were killed as a result of a single event whose probability of occurrence was dose dependent, then the cell survival curve would be exponential. However, there is a shoulder on most mammalian cell survival curves, followed by an exponential fall-off at higher doses (see Figure 22.1).

The model of cell survival, in most common clinical use today, is the linear-quadratic (LQ) model [11]. In this model, the cell survival is given by

$$S = e^{-\alpha d - \beta d^2} \tag{22.1}$$

Thomas' Hematopoietic Cell Transplantation, Fifth Edition. Edited by

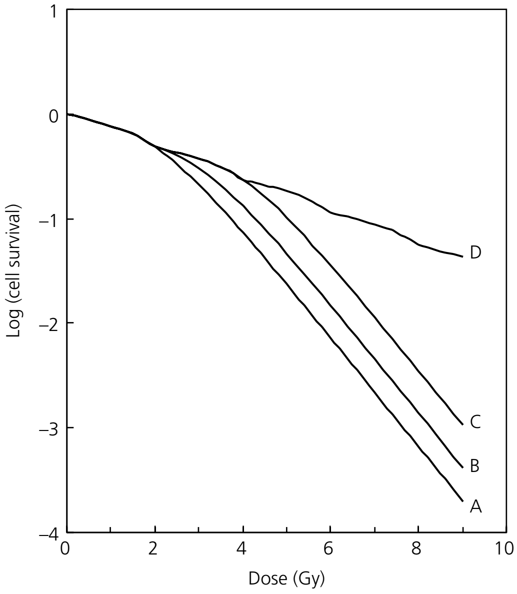

Figure 22.1 Cell survival curve for a multi-hit single target model. Curve A shows the cell survival for a single dose. Curve C shows the cell survival following a completely repaired single dose of 2 Gy. Curve B shows the cell survival after incomplete repair of the initial 2 Gy fraction. Curve D shows the cell survival for multiple 2 Gy fractions.

where the first term in the exponent can be interpreted as being the single-hit component of cell killing (e.g., double strand breaks) and the second term is the two-hit component (e.g., single strand breaks). Clearly, this model is incompatible with a model that has a linear high-dose behavior (in log$S$), but over the range of usual applicability (less than 10 Gy), the models are often indistinguishable. For N fractions, the cell survival is given by

$$S=\left(e^{-\alpha d-\beta d^2}\right)^N=e^{-\alpha D-\beta Dd} \qquad (22.2)$$

where $D = dN$ is the total dose given in N fractions of size d.

The shoulder of the cell survival curve is a result of the repair of sublethal damage (SLD) [12]. SLD consists of intracellular lesions that are not lethal by themselves, but that may combine with other such lesions to produce a lesion that leads to cell death. For example, a single strand break on the DNA would not be lethal, but two single strand breaks in close proximity would produce a lethal double strand break. Repair of SLD is thought to be complete in less than 24 hours, the normal interfraction interval in radiation oncology. However, mean repair times are generally estimated to be in the range 1–4 hours, a time that becomes important when considering treatments with multiple fractions per day (hyperfractionation). During this repair time, the shoulder on the cell survival curve is being restored, so that when repair is complete, an additional fraction has the same probability of killing a cell as the initial fraction of the same dose. If there is no repair, then the two doses add arithmetically as if they were given in one single dose, producing a much lower cell survival. If the repair is partially complete, then the cell survival is intermediate. This effect is depicted in Figure 22.1. Curve A shows a single dose cell survival curve; curve C shows the cell survival curve for a second dose following an initial dose of 2 Gy and complete repair. Curve B is the same as curve C except that the timing of the second dose is such that repair is not complete after the initial 2 Gy. Curve D shows the cell survival curve for a series of 2 Gy fractions with complete interfraction repair. If there is no shoulder on the cell survival curve, then there is no advantage to fractionation in terms of cell survival.

The same mechanism that gives rise to the shoulder on the cell survival curve is also responsible for the dose-rate effect. If the cell survival curve has no shoulder, then it is generally believed that there will be no dose-rate effect and there will also be no fractionation effect. As opposed to most normal tissues, both leukemia and lymphoma cells are usually seen to have little or no shoulder. Therefore, in HCT, a therapeutic benefit is gained by lowering the dose rate or by fractionating the dose, but not necessarily by both. The more the dose is fractionated, the more cells are killed by the single-hit mechanism, and the less impact the dose rate will have.

The ratio of the parameters in equation (22.2)22.2, α/β, has clinical implications [12]. Higher values of α/β mean that the tissue will be less sensitive to a specific fractionation schedule and more dependent on the total dose. Lower values mean that the tissue's response will be more sensitive to dose per fraction. Generally, late responses are characterized by lower values of α/β (1–3 Gy), whereas acute responses are associated with higher values (~10 Gy).

To conclude, the radiobiologic principles summarized above help to explain why fractionated TBI is less toxic than single-dose TBI for the same level of malignant cell kill. Most TBI regimens are designed to be completed in 1 week, and therefore to increase fractionation beyond five fractions one must treat with multiple fractions per day. To maximize repair of sublethal damage, an interfraction interval of at least 6 hours should be used. Not only does this make three fractions per day logistically difficult, but also the radiobiologic impact of three fractions per day may be unpredictable. However, there are a number of standard fractionation regimens that employ three fractions per day successfully. Comprehensive statistical analysis of the comparative results from one, two, and three fractions per day is not yet available.

Radiation physics and physical considerations

There are a large number of papers and reports that give details on the planning and delivery of TBI [13,14]. Discussed below are the principles that guide this treatment.

TBI treatment is the least conformal treatment that is given in radiation oncology. The primary technical concern is to deliver the desired dose to the entire patient. The most straightforward way to accomplish this objective is to irradiate the entire patient in a single radiation beam. This is achieved by using a large (approximately 4 m) source-to-skin distance (SSD) and the largest practicable field size. The large SSD reduces the dose rate to about 10% of that which is typically used in radiation therapy. The typical field arrangement is to have the patient standing on a specially designed stand, to rotate the collimator by 45° to utilize the diagonal dimension of the field, to use lead strips as compensating filters to achieve a uniform dose rate (at midline) from head to foot, to use a Plexiglas barrier close to the patient to defeat the skin-sparing effect of high-energy photons, and to block critical organs (usually the lungs, sometimes the kidneys, liver, and previously irradiated sites) to lower the dose to these tissues. The patient is treated with anterior and posterior fields, often given on alternating treatment sessions. Alternatively, the patient may be treated while lying on a gurney or a specially designed table at floor level. Treating on or near the floor is common in pediatric cases where the field size requirements are not as great. Because the SSD is

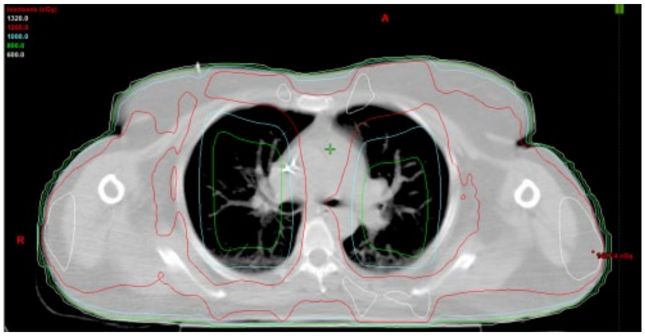

Figure 22.2 Dose distribution through T5–6 showing 6, 8, 10, 12, and 13.2 Gy isodose lines. The prescription dose was 12 Gy, with 50% attenuation lung blocks. (For a color version of this figure, please see the color plate section.)

shorter, this technique will produce a higher dose rate unless the machine's output rate can be electronically adjusted.

On modern C-arm linear accelerators, the dose rate at isocenter is adjustable. This is often used to achieve a dose rate dictated by a particular clinical trial. The selection of beam energy is not critical, with most treatment centers using photon energies between 6 and 10 MV. Photons with these energies have a skin-sparing effect produced by the buildup of forward scattered electrons until electronic equilibrium is established. (Electronic equilibrium is characterized by the same number and energy of electrons being scattered into a region as are scattered out of the region.) Because of this reduced skin dose, a beam spoiler of low atomic number material is placed close to the patient. Electrons scattered from this material to the patient increase the skin dose. This is done to achieve full dose on the skin surface, but the assumption that clonogens are always present on the skin surface has not been proven.

The dose is usually measured at several points on the patient's body with the goal of achieving a uniform dose within ±5%. To achieve this, a compensating filter is constructed of thin lead sheets on a Plexiglas tray inserted in the beam. This filter is designed to compensate both for the variations in patient thickness and for the variation in beam intensity away from the center of the beam.

Most treatment regimens now require the shielding of certain sensitive structures, with the lung being the most common of these. One reason why the AP/PA fields are often preferred is that they allow the most accurate method for supplementing the dose to the chest wall when the lung is blocked. If no lung blocking is used, then the dose to the lung is higher than the dose to midline by as much as 10%. This increase is a result of the reduced attenuation in the lung, the density of which is about one-third of that of most soft tissues. Typically, when lung blocks are used, the blocks cover the central portion of the lung, with about 1–2 cm between the edge of the lung shadow on the film and the edge of the block. It is also typical not to use full-thickness lung blocks, which have a transmission factor of 3%, but rather to use blocks that transmit 50% of the primary beam. The areas of the chest wall that are shielded by the lung blocks are then treated with supplemental electron fields whose beam energy and dose contribution are calculated to bring the dose to the pleural surface to the prescribed value. Figure 22.2 shows the dose distribution at the level T5–6 for a TBI treatment of 12 Gy total dose with 50% transmission blocks over the lungs and supplemented with 9 MeV electrons. The effect of the beam spoiler is not included.

High-dose TBI-containing regimens: clinical results

High-dose TBI schedules utilized

The first use of TBI, reported by Thomas et al. [1] in a twin HCT study, delivered the dose in a single fraction. Although engraftment was successful in both patients, relapse occurred within 12 weeks, suggesting that TBI alone was insufficient to prevent relapse. Since then, high-dose chemotherapy, usually with cyclophosphamide (CY), has been combined with TBI. A randomized trial found no difference in overall survival and remission between CY and TBI versus melphalan (MEL) and TBI [15]. Typical TBI schedules deliver a total dose of 10–14 Gy at 1.2 Gy three times daily (TID), 2 Gy twice daily(BID) or 3 Gy once daily (QD). A variety of TBI schedules have been evaluated to reduce toxicities, decrease relapse rates, and improve further the therapeutic index. Factors that are of radiobiologic importance include total dose, fraction schedule, fraction size, use of organ shielding, and dose rate. Only a few randomized trials have been performed and most trials involved changes in multiple variables, making determination of the optimal TBI schedule difficult.

Single-fraction versus multi-fraction schedules

Early studies compared fractionated with single-fraction schedules. Fractionation offered the potential to reduce organ toxicities without compromising tumor control, given the greater ability of most normal tissues to repair sublethal radiation damage compared with leukemia cells [9]. Retrospective analyses from the groups at Johns Hopkins University [16] and the Memorial Sloan Kettering Cancer Center [17] reported a reduction in interstitial pneumonitis (IP) with lung shielding and fractionated TBI (FTBI) (one fraction per day) or hyperfractionated (HFTBI) (multiple fractions per day) schedules compared with single-fraction TBI (STBI) and no lung shielding. An update of the Memorial Sloan Kettering Cancer Center experience by Shank et al. [18] reported a reduction in IP incidence from 50% with STBI to 4% with HFTBI and lung shielding.

Subsequent studies comparing single- versus multi-fraction schedules have reported mixed results [19–21]. Ozashin et al. [20] found no significant differences in relapse rate, survival, or incidence of IP or sinusoidal obstruction syndrome (SOS) in patients receiving 10 Gy STBI compared with 12 Gy (2 Gy BID) HFTBI. A report analyzing the experience of multiple institutions in the Children's Cancer Study Group [19] of patients with acute myeloid leukemia (AML) in first remission treated with 7.5–10 Gy STBI or 12–13.2 Gy FTBI (2 Gy BID or 1.2 Gy TID) reported a reduction in 2-year relapse rate from 23% to 0% ($p = 0.07$) in favor of HFTBI, but no significant differences in survival or incidence of IP. A single institution experience by Cosset et al. [22] observed no difference in relapse rate or overall survival, but documented a reduction in treatment related mortality (55% versus 26%) and a statistically significant reduction in incidence of IP (45% versus 13%) and graft-versus-host (GVHD) (77% versus 43%) with 13.2 Gy (1.2 Gy TID) HFTBI compared with 10 Gy STBI. Finally, a large retrospective analysis of the experience from 21 institutions in France [21] also reported a significant reduction in incidence of IP (37.5 % versus 1.7%) and GVHD (41% versus 22%) with a hyperfractionated schedule (10–13.2 Gy) compared with a single fraction of 10 Gy. However, no change in survival and an increase in relapse rate were observed with hyperfractionation (29% versus 16%, $0.5 < p < 0.1$).

Two randomized trials have compared single-fraction with multi-fraction TBI. A trial from Seattle [23] compared 10 Gy STBI with 12 Gy HFTBI at 2 Gy BID in patients with AML in first remission. HFTBI resulted in a reduction in idiopathic IP (4% versus 11%), a decrease in relapse rate (12% versus 22%), and a statistically significant increase in 5-year overall survival of 54% versus 33%. A more recent French study [24] randomized patients to receive 10 Gy STBI or 14.85 Gy HFTBI at 1.35 Gy TID and reported a statistically significant decrease in SOS (4% versus 14%) with HFTBI. No difference in IP incidence was observed between the two groups. Eight-year cause-specific and overall survival with HFTBI were 77% and 45%, respectively, compared with STBI with 63.5% and 38%, respectively. TBI schedule was an independent prognostic factor by multivariate analysis if cause-specific survival was the end-point.

In summary, most studies document a reduction in toxicities with fractionated or hyperfractionated TBI schedules. This is consistent with the radiobiologic principles described earlier. Many studies, including the two randomized trials, also document improved relapse and survival rates with multi-fraction as opposed to single-fraction schedules. The majority of TBI schedules used today are fractionated or hyperfractionated.

Total dose and dose escalation

Fractionated schedules and the resultant reduction in toxicities allow the possibility of increasing total dose and improving outcomes. The Seattle group carried out two randomized trials comparing CY combined with 12 Gy at 2 Gy/day or 15.75 Gy at 2.25 Gy/day. In a trial of 116 patients with chronic myelogenous leukemia (CML) in chronic phase, the higher dose resulted in a significantly lower relapse rate (0% versus 25%, $p = 0.008$), but higher treatment-related mortality rate (24% 12 Gy and 34% 15.75 Gy, $p = 0.13$), and as a result no significant change in overall survival [25]. In a separate report of 71 patients with AML in first remission, relapse rate was also decreased with the higher dose (14% versus 39%, $p = 0.06$), but these gains were offset by an increase in non-relapse mortality (38% versus 19%, $p = 0.05$), resulting in no difference in overall survival between the two arms [26].

Reports from other groups also suggest that higher doses have greater antileukemia effects. In several retrospective reports from the group in Genoa [27], relapse rate and survival were significantly decreased if the TBI dose was >9.9 Gy (3.3 Gy/day). In an analysis of the Center for International Blood and Marrow Transplantation Research (CIBMTR) and City of Hope Cancer Center databases, Marks et al. [28] reported that patients with acute lymphoblastic leukemia (ALL) beyond first remission receiving TBI–CY conditioning regimens had a lower relapse rate and increased disease-free survival if the TBI dose was ≥13 Gy.

Kal et al. [29] compared results of different TBI regimens published in three randomized trials, four studies comparing results of two to three TBI regimens, and nine studies reporting on one TBI regimen. Using linear quadratic principles, a biologically effective dose (BED) was calculated for each TBI regimen to normalize for differences in dose per fraction, number of fractions, and dose-rates of the different regimens. Higher BED values were associated with a lower relapse rate and higher disease-free survival and overall survival rates.

Other reports found no clear advantage of higher doses. A single institution retrospective analysis of 116 patients found an inverse correlation between overall survival and TBI doses of 10, 12 and 13.5 Gy given in six fractions over 3 days [30]. Phase I trials have been performed with increased toxicities but observed no obvious benefit with increasing TBI dose [31–33]. Peterson et al. [32] determined a maximum tolerated dose (MTD) of 16 Gy (2 Gy BID) when combined with CY 120 mg/kg. The primary dose-limiting toxicity was pneumonitis, followed by SOS, nephrotoxicity, and mucositis. Demirer et al. [31], also using a TBI–CY regimen, observed no additional benefit with higher total doses of 14.4 Gy at 1.2 Gy TID in patients with ALL and non-Hodgkin lymphoma (NHL). Alyea et al. [33] escalated dose in a TBI–CY regimen from 14 to 15.6 Gy. Acute GVHD and treatment-related mortality were higher at 15.6 Gy, but no improvement in relapse rate or overall survival was observed.

Other phase I trials have escalated TBI doses without concomitant chemotherapy. Results of a limited phase I TBI dose escalation trial without chemotherapy were reported in patients with NHL undergoing autologous HCT [34]; 50% lung attenuation blocks and blocks to limit the kidney dose to 15 Gy were utilized. The highest dose reached was 20 Gy (2 Gy BID), which was considered to be associated with acceptable toxicities. IP or SOS was seen in only one of nine patients. A dose escalation trial of TBI without concomitant chemotherapy was also carried out by the Seattle group [35]. Patients with primarily bone-only metastatic disease from a variety of hematologic and solid tumors first received high-dose chemotherapy [busulfan (BU), MEL, *N*-triethylenethiophosphoramide (thioTEPA), then a median of 105 days later underwent TBI as part of a tandem autologous HCT trial. Although 90% attenuation lung and liver blocks were utilized, the highest TBI dose achieved was only 15 Gy with grade 3 and 4 IP being dose limiting.

In summary, despite the use of fractionated schedules and organ shielding, escalation of TBI dose has been difficult owing to dose-limiting normal tissue toxicities, which have primarily been pulmonary. This has limited total doses of most conditioning regimens to approximately 16 Gy or less. Trials attempting to demonstrate improved relapse and survival rates with increasing TBI dose have reported mixed results, perhaps because the magnitude of dose escalation has been limited. Gains in disease control are associated with an increase in regimen-related toxicities and non-relapse mortality in some studies, resulting in no improvement in overall survival. New strategies are clearly needed to allow further dose escalation without an associated increase in side effects.

Fractionated versus hyperfractionated schedules and fraction size

Daily fractionated schedules have used fractions of approximately 2.25–4.67 Gy. Hyperfractionated schedules are usually delivered at 1.2–2 Gy fractions a minimum of 5–6 hours apart. In general, larger fractions are predicted to be associated with greater normal organ effects, potentially reducing the therapeutic index. To date, no randomized trials have been performed that specifically addressed these factors. The available clinical data suggest that larger daily fraction schedules are acceptable [36,37], although most schedules using ≥3 Gy fractions have limited the total dose to 9.9–12 Gy.

In a retrospective analysis of patients with high-risk NHL undergoing autologous HCT, Gopal et al. [38] compared groups treated to 10.2 Gy at 1.7 Gy BID with those treated to 12 Gy at 3 Gy per day. No differences in overall survival or in acute or late pulmonary complications were seen. The 3-year freedom from late pulmonary complications was 80% for the 10.2 Gy group and 70% for the 12 Gy group ($p = 0.45$). Three-year freedom from progression was significantly lower for the 12 Gy group (82% versus 31%, $p < 0.001$). Of note, lung shielding was not utilized for the 10.2 Gy group, but was utilized in the 12 Gy group after the third fraction. In addition, the total dose of 10.2 Gy is lower than what other hyperfractionated schedules deliver, raising the possibility that the two schedules did not deliver biologically equivalent doses. This may explain in part the differences observed.

Consistent with this are the results of Corvo et al. [39], who retrospectively reviewed their experience with patients undergoing unrelated donor HCT. Comparisons were made between patients treated to 9.9 Gy at 3 Gy per day and those treated during an earlier period to 12 Gy at 2 Gy BID. Lung shields were used in both groups. The actuarial 5-year transplant-related mortality rate was 31% for the HFTBI group and 41% for the FTBI group ($p = 0.1$). For the HFTBI group, there was a statistically significant improvement in the 5-year leukemia relapse rate (13% versus 31%, $p = 0.04$) and over all survival rate (68% versus 51%, $p = 0.01$). It was concluded that the improved results were primarily related to the higher total doses delivered with the HFTBI schedule.

Dose rate

TBI is delivered at relatively low dose rates, usually in the range 5–30 cGy/min. This is lower than those used with standard external beam radiotherapy to more localized sites in the body, which are typically greater than 100 cGy/min. Radiation delivered at a lower dose-rate can potentially be more organ sparing. However, dose-rate effects may be greatest and most clinically important primarily at very low dose-rates. Travis et al. [40] evaluated out to 1-year survival and histologic changes in mice receiving TBI at dose rates ranging from 1 to 25 cGy/min. A direct correlation was seen between dose rate and survival and also dose rate and histologic changes in lung and kidney. The dose-rate effects were greatest for dose rates ranging from 1 to 5 cGy/min. Consistent with this are the observations of Weiner et al. [41], who reported on 932 patients in the IBMTR database treated from 1978 to 1983 and observed a decrease in incidence of pneumonitis with lower dose rate but only in patients treated at less than 6 cGy/min.

The potential clinical benefits of using lower dose-rates are probably outweighed by other factors such as fractionation or organ shielding. Sampath et al. [42], in a multivariate logistic regression analysis of TBI in 1090 patients from 20 published studies, found an inverse correlation with pneumonitis incidence and fractionation, but no dose-rate effect. A preclinical study by Tarbell et al. [43] reported a higher radiation-related mortality rate in mice receiving STBI at a high dose rate (80 cGy/min) compared with STBI at low dose-rate (5 cGy/min). Dose-rate effects were not seen with BID or TID fractionation schedules, suggesting that fractionation was a greater factor in normal organ sparing than dose-rate effects.

In a multi-institution randomized trial from France [20], 157 patients were randomized to either higher or lower dose-rate groups. TBI was delivered either as a single fraction of 10 Gy or hyperfractionated to 12 Gy at 2 Gy BID, determined by physician preference and not randomization. The dose rate for the 10 Gy STBI group was 6 versus 15 cGy/min and for the 12 Gy HFTBI group 3 versus 6 cGy/min. No statistically significant difference in survival or incidence of IP or SOS was seen with dose rate or fractionation schedule. Of note, the highest estimated 4-year incidence of IP occurred in the single-fraction high dose-rate group (49.1%), compared with 29.5% in the single-fraction low dose-rate group. The incidence of cataracts was lower in the lower dose-rate groups (3.5%) compared with the higher dose-rate groups (14%).

A subsequent retrospective analysis of 326 patients by Belkacemi et al. [44] compared patients treated at low (<4.8 cGy/min), medium (4.8–9 cGy/min), and high (>9 cGy/min) dose rates, and also reported a statistically significant reduction in cataract incidence of 0% with lower dose rate compared with 27% with medium and 33% with higher dose-rates ($p = 0.0001$). A significant decrease in IP was also seen with a 48% incidence for the higher dose rate versus and a 19% incidence for the medium dose rate groups ($p = 0.05$). Survival and treatment-related mortality rates were not influenced by dose rate.

More recently, Carruthers and Wallington [45] retrospectively analyzed their institution's experience of 84 patients treated with 12 Gy TBI (2 Gy BID) at either 15 or 7.5 cGy/min. IP was observed in 43% treated at the higher dose rate compared with only 13% at the lower dose rate. A similar conclusion was reached by Beyzadeoglu et al. [46] in an analysis of 105 patients where IP incidence was greater in patients treated at a dose rate of >4 cGy/min.

Higher dose rates on the order of 30–90 cGy/min have been used with acceptable toxicities, but the total dose was limited to 5–5.5 Gy, making direct comparisons with other studies difficult [47,48]. Bredeson et al. [49] reported acceptable toxicity in 142 patients receiving TBI at 80 cGy/min. Although the majority received 5 Gy in a single fraction, 48 patients received 12 Gy at 2 Gy BID without lung shielding.

In summary, although the range of dose rates utilized for TBI is limited, reducing the dose rate within this range appears to result in a reduction in incidence of cataracts and, according to some reports, pneumonitis. This appears to occur without a detrimental affect on survival or relapse rates in most studies. The clinical data suggest that dose-rate effects can be seen with both single- and multi-fraction schedules, although data from animal models indicate a reduction in dose-rate effects with fractionation. Based on the available clinical data, the importance of dose-rate effects on TBI outcomes at levels greater than approximately 30 cGy/min is unknown.

Organ shielding

The primary dose-limiting toxicity of TBI is pulmonary. The use of shielding to reduce the total dose to lungs has been shown to decrease the incidence of pneumonitis and is now routinely used at many centers. Median lung doses with shielding have usually been limited to approximately 8–10 Gy. Shank et al. [18] reported a reduction in IP incidence from 50% with STBI and no lung shielding to 4% with HFTBI and lung shielding. Volpe et al. [50] reported a 3.8% incidence of lethal pulmonary complications if lung dose was ≤9.4 Gy compared with 14.3% if >9.4 Gy. Lawton et al. [51] noted lethal pulmonary events in 6/11 patients with 50% lung attenuation blocks compared with 22/107 if lung shielding with 60% attenuation blocks was used. A randomized trial was performed by Labar et al. [36] to assess the impact of lung shielding. Eighty two patients received a TBI dose of 12 Gy (4 Gy/day) and lung blocks if used were placed after 9 Gy. The incidence of IP decreased from 15% to 5% with the use of lung blocks.

Renal shielding has also reduced nephrotoxicity after TBI. The group at the Medical College of Wisconsin noted at 18 months a 29% incidence of nephropathy without shielding compared with 0% with kidney shielding in patients receiving 14 Gy HFTBI [52]. Another study explored the use of extensive lung and liver shielding in patients with multiple myeloma undergoing autologous HCT [53]. Patients first received induction with vincristine–adriamycin–dexamethasone (VAD), followed by TBI/BU/CY using 90% attenuation lung and liver blocks with electron boost to portions of the chest wall underlying the blocks. The total dose was 9 Gy at 1.5 Gy BID. Complete response rates of 48% and 41% were seen in patients with de novo and pretreated multiple myeloma, respectively. The transplant-related mortality rate was 2%. Grade III/IV mucositis was observed in 75% and three patients developed reversible SOS.

It was concluded that with lung and liver shielding, TBI can be combined with BU and CY with acceptable toxicity and encouraging response rates.

One group has reported a potential detrimental effect of shielding. A study by the Seattle group [54] found that shielding increased relapse rates in patients with refractory anemia undergoing allogeneic HCT. In this study, 14 patients were treated with CY and TBI to 12 Gy at 2 Gy BID (10 patients) or <12 Gy (four patients) utilizing 95% attenuation lung and right hepatic lobe blocks. The underlying chest wall was then boosted with electrons using an approach similar to that reported by Shank et al. [18]. When compared with historical controls, there was an increase in relapse rate (34% versus 2%, $p = 0.0004$) and a decrease in disease-free survival (38% versus 61%, $p = 0.16$). No difference in non-relapse mortality was seen. It was hypothesized that 95% shielding may have shielded malignant cells or reduced immunosuppression and graft versus leukemia effect.

High-dose TBI-containing regimens: normal tissue effects

Most of the published clinical experience using TBI is in combination with high-dose systemic chemotherapy. Some of the agents frequently administered with TBI include CY [17], etoposide (VP16) [55], MEL [56], cytarabine [57]. and thioTEPA [58]. These agents are cytotoxic and result in acute and late toxicities that are often similar to those with TBI, including nausea, vomiting, mucositis, esophagitis, diarrhea, hepatic dysfunction, pneumonitis, gonadal dysfunction, and second malignancy induction. Therefore, identifying toxicities and outcomes attributable solely to TBI is difficult and the published literature more accurately represents the clinical results with TBI-containing regimens as opposed to TBI alone.

In summaries of the HCT literature, it is very common to compare the outcomes for single-fraction with those for fractionated dose schedules without regard to the total dose or dose per fraction. In virtually every normal tissue at risk in radiation therapy, one can reduce the morbidity by increasing fractionation or, equivalently, decreasing the dose per fraction. Hence simply to ask whether fractionation ameliorates the side effects is not sufficient, since it can be assumed a priori. The more relevant questions are whether there is a demonstrable dose response, how much benefit there is to fractionation, whether there is added benefit to hyperfractionation, and what comorbidities or other treatments may impact the response.

There are numerous side effects and complications from HCT. In this section, we address primarily those complications that limit the dose of radiation that can be given. Other complications that may be due at least in part to the radiation, but either occur at a low incidence for most transplant regimens, are not associated with sufficient morbidity to limit the dose, or do not appear to demonstrate a dose response, are mentioned but are not discussed in detail.

Acute toxicities associated with high dose TBI-containing regimens

Fractionated (one fraction per day) or hyperfractionated (multiple fractions per day) TBI schedules, compared with single-fraction schedules, result in reduced acute toxicities, and are better tolerated [18,20,44]. Nausea and vomiting are the most common side effects observed, occurring in approximately 35–50% of patients [20,59,60]. In studies conducted prior to the use of modern antiemetics, Spitzer et al. [61] reported emesis in all patients after the first 1.2 Gy fraction of hyperfractionated TBI, but a decline with subsequent fractions. Buchali et al. [59], using a 12 Gy hyperfractionated regimen, reported an increasing incidence of emesis with each 1.5 Gy fraction up to the third fraction, with a constant incidence with subsequent fractions. Antiemetics such as ondansetron and granisetron can significantly reduce the incidence and severity of emesis [62,63].

Transient parotiditis occurs in approximately 10–30% of patients undergoing fractionated TBI with a higher incidence (25–75%) associated with single-fraction schedules [59,60]. The onset is usually after the first fraction, with resolution over the next 24–48 hours. Xerostomia and xerophthalmia can occur in approximately 15–30% of patients [59,60].

Mucositis is also observed in approximately 40–100% of patients in the days after completing TBI and can be influenced by the chemotherapy used. For example, mucositis is a primary acute toxicity with etoposide-containing regimens [55]. Mucositis observed with TBI combined with high-dose MEL limited the feasibility of this combination [64]. Diarrhea can also occur in the days after completing TBI in 10–35% of patients. Other acute side effects include fatigue, decreased appetite, erythema, esophagitis, and alopecia.

More recent studies provide some indication of the acute toxicities primarily related to TBI alone. Zaucha et al. [35], in a phase I dose escalation trial, treated patients with a tandem autologous HCT approach, first with high-dose BU, MEL, and thioTEPA, followed a median of 105 days later by TBI to a total dose of 12, 13.5, or 15 Gy at 1.5 Gy BID. Acute toxicities were primarily grade 1–2 (by Bearman regimen-related toxicity scale [65]) with mucositis occurring in 100%. Gastrointestinal, skin, renal, and hepatic grade 1–2 acute toxicities occurred in 34, 19, 9, and 9%, respectively. In a limited phase I dose escalation study, McAfee et al. [34] reported mucositis in 88% and nausea in one-third of patients receiving 16, 18, or 20 Gy TBI alone at 2 Gy BID.

GVHD is known to increase the risk of some of these complications, and can occur with both TBI- and non-TBI-containing conditioning regimens. In some clinical studies TBI does not appear to increase the risk of GVHD over non-TBI conditioning regimens [66–68], although one randomized trial reported a greater incidence of acute GVHD with TBI–CY versus BU–CY [69]. Development of GVHD is probably related more to the intensity of the regimen rather than to TBI itself. In experimental models, the incidence of GVHD is increased with higher TBI doses [70] or with the addition of CY to TBI [71]. The initiating event is thought to involve damage to the intestinal mucosa by the conditioning regimen, resulting in release of lipopolysaccharide into the circulation, release of TNF-α, and subsequent increase in expression of host major histocompatibility antigens, enhancing recognition by donor T cells.

Lung: interstitial pneumonitis

IP is a clinically important complication of TBI in patients undergoing HCT. Kim et al. defined IP as "a condition in which a patient develops interstitial pulmonary infiltrates on chest X-ray with or without patchy alveolar infiltrate. The patient produces scanty non-purulent sputum which is negative in culture for bacterial and fungal infection" [72]. Experimental and clinical data have confirmed that fractionated TBI is less toxic to the lung than single-dose TBI [16,18,22]. Fractionated doses above 15 Gy [73] are associated with higher incidences of IP. IP also occurs in conditioning regimens that do not include TBI at all. BU alone is associated with a crude incidence of IP of 4–10%. It is known that chemotherapy, particularly using alkylating agents given with TBI as part of the bone marrow transplantation (BMT) procedure, contributes to pulmonary

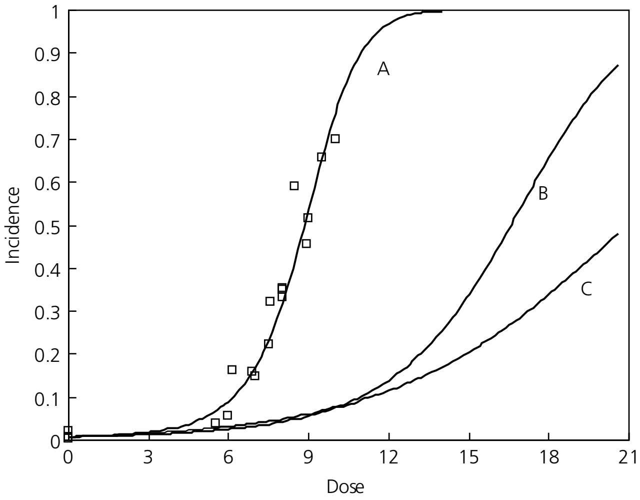

Figure 22.3 Dose response for IP. Curve A is the single-fraction dose response with data from Sampath et al. Curve B is the five-fraction dose response. Curve C is the dose response for 2 Gy per fraction.

toxicity. This makes it difficult to distinguish TBI toxicity from other etiologies of lung damage [38].

To investigate the radiation dose response and the other factors that may affect the incidence of IP, Sampath et al. reviewed the literature, selecting papers that included sufficient data for a multivariate analysis (MVA) including dose, dose rate, chemotherapy regimen, and other variables [42]. The final number of articles included was 20, with a total of 26 TBI/chemotherapy conditioning regimens. Five regimens had no TBI and four had no chemotherapy (upper half body treatments). These figures reflect only those regimens in which patients received *daily* fractionation. The data for multiple fractions per day had too much dispersion to be fitted by logistic regression. Figure 22.3 shows the dose response obtained from MVA, illustrating the dose-response functions for one fraction, five fractions, and for daily fractions at 2 Gy per fraction. These dose response functions reflect the response to radiation only. The addition of CY and many other chemotherapeutic agents is associated with higher rates of IP. The findings of Sampath et al. indicated that there was no dose-rate effect for IP on MVA. The odds ratio for 120 mg/kg of cyclophosphamide was 5.9. The α/β ratio (from the LQ model) was 2.8 Gy.

The low value of the α/β ratio indicates that IP is significantly diminished with increasing fractionation. However, direct analysis of data from hyperfractionation regimens has not been possible. This could be due to the complex repair of sublethal damage to the lung. There appears to be a slow repair component that would at least partially offset the beneficial effects of hyperfractionation [74].

Other pulmonary side effects include idiopathic pneumonia, radiation fibrosis, and diminished lung function.

Renal toxicity

Renal damage is expressed up to about 2 years after treatment. It is characterized by reduced filtration rates, increased BUN and creatinine, proteinuria, hypertension, and anemia. Ozsahin et al. found no difference in renal toxicity among groups in a randomized trial comparing 10 Gy single fractions to 12 Gy in six fractions and using two different dose rates [20].

In a study combining literature reports of renal damage after TBI, Kal and van Kempen-Harteveld reported their findings regarding the dose response after assuming an α/β ratio of 2.5 Gy and a repair half-time of 2 hours [75]. However, fractionation parameters were not analyzed, but rather assumed, and no accounting was made for regimens in which highly nephrotoxic drugs were used. Using 24 regimens from 12 studies, Cheng et al. [76] investigated the impact of total dose, dose rate, dose per fraction, number of fractions, fractions per day, interfraction interval, age (pediatrics versus adults versus mixed), and chemotherapy on renal toxicity following HCT. A dose response was seen in the adult population but not in the pediatric population. Dose rate was significant but only below 10 cGy/min. The commonly used schedule of six times 2 Gy is associated with a renal toxicity rate of about 10%. Teniposide and cyclosporine were associated with relative risks of 10.5 and 5.9, respectively, in pediatric patients; fludarabine had a relative risk of 6.2 for adults Although Kal and van Kempen-Harteveld [75] estimated the tolerance dose for the kidney in TBI to be approximately 16 Gy, Cheng et al. found the dose associated with 10% incidence of late renal toxicity to be 10–12 Gy [76].

Sinusoidal obstructive syndrome

Sinusoidal obstructive syndrome (previously termed veno-occlusive disease) is a dose-related and potentially fatal complication of the HCT conditioning regimen. It is much more common in regimens where the TBI is replaced with BU [66–68]. However, even with TBI regimens, the incidence can be up to 10%. Although a lower incidence is generally found with fractionated radiation [24], the dependence on radiation dose is modest. Only one case (11%) was seen in nine patients treated with doses of 16–20 Gy in 2 Gy fractions in a phase I dose escalation study [34], and Ozsahin et al. found six cases in 100 patients treated with 12 Gy in six fractions [20]. There appears to be no dose-rate dependence for fractionated treatment, although there is some evidence for a single-fraction dose-rate effect below 7 cGy/min [77].

Cataract formation

Cataract formation occurs up to 10 years after HCT, and the cumulative incidence can reach 100% [78]. A dose response for cataract formation was shown by van Kempen-Harteveld et al. in a multi-institutional study [78]. (Although they assumed a dose-rate effect, statistical analysis presented in their paper argues against it.) They reported an α/β ratio of 0.75 Gy, indicating that cataractogenesis should be very sensitive to fractionation. In addition, treatment with steroids (for GVHD) and heparin shifted the dose–response curve to the left, but they did not determine relative risks associated with these drugs. This study has the advantage that incidence of cataracts was determined using actuarial methods rather than crude incidence. Because of severe censoring, using crude incidence may not produce reliable results. In a different study, van Kempen-Harteveld et al. showed that shielding the lens in the anterior field reduced the incidence and severity of cataract formation while increasing the latency without increasing central nervous system (CNS) recurrence [79].

For CML, Socié et al. reported a hazard ratio of 2.3 for TBI-associated cataractogenesis compared with BU regimens in a summary analysis of four randomized trials [68]. However, in AML, there was no difference in the two conditioning regimens. Also, chronic GVHD was associated with a hazard ratio of 2.6, but only for CML. Belkacemi et al. [44] and Ozsahin et al. [20] found a protective effect for dose rates lower that 4 and 6 cGy/min, respectively.

Second malignancy induction

There is no question that ionizing radiation can induce carcinogenic transformations. However, the risk of second solid tumors resulting from TBI has been overstressed in the literature. In a study of more than 19,000 HCT patients, an excess of 50 cancers were seen [80]. Even if every one of these was attributable to radiation, the absolute incidence is less than 0.3%. In fact, in MVA of these data, only fractionated radiation to TBI doses higher than 14 Gy and limited-field irradiation were associated with a significantly increased incidence of invasive solid tumors. In two separate single-institution analyses of over 4200 patients, TBI was not significantly related to induction of second solid tumors on MVA, despite the inclusion of basal cell cancers, accounting for nine out of the 46 solid malignancies [81,82]. It is clear that the incidence of radiation-induced solid malignancies from TBI, although occurring, is just barely above the background and can be detected only in populations on the order of 10^4 or higher. The risk is apparently higher among children than adults [83].

There is continued debate as to whether TBI contributes to the risk of developing MDS after autologous HCT. In addition to TBI, other possible contributing factors include the amount and type of pretransplant chemotherapy, pretransplant radiotherapy, the specific conditioning regimen, stem-cell priming regimens, source of stem cells, selection criteria used for TBI, and length of follow-up between TBI- and non-TBI-treated cohorts. These factors are difficult to control for in any retrospective analysis. A number of retrospective studies have reported TBI as an independent risk factor for MDS in patients with NHL [84,85] and Hodgkin lymphoma [86]. However, Krishnan et al. [87], in a retrospective analysis of 218 patients at City of Hope Cancer Center, did not find TBI to be an independent risk factor. Only priming with etoposide was a risk factor. Harrison et al. [88], in a case-controlled study of 595 patients with Hodgkin disease, found extent of pretransplant therapy and pretransplant exposure to lomustine or the combination of mechlorethamine, vincristine, procarbazine and prednisone to be risk factors, but not autologous HCT.

Other late effects of TBI may include growth retardation, neurocognitive effects, gonadal dysfunction, and late cardiomyopathy. Because of the highly censored population and the possibility of competing risks, analysis of the contribution of TBI to very late effects is extremely difficult.

High-dose TBI versus non-TBI regimens

Multiple randomized trials and non-randomized studies have been performed comparing TBI- versus non-TBI-containing high-dose conditioning regimens. Most studies have compared TBI–CY with BU–CY regimens. Results of select randomized trials are summarized in Table 22.1.

A number of randomized trials demonstrate an advantage for TBI-containing regimens. Blaise et al. [89] randomized patients with AML in first complete remission to TBI–CY (120 mg/kg) or

Table 22.1 Select randomized trials comparing TBI- with non-TBI-containing high-dose HCT conditioning regimens

BU (16 mg/kg)–CY (120 mg/kg). A statistically significant improvement in 2-year disease-free survival (72% vs. 47%), overall survival (75% vs. 51%), relapse rate (14% vs. 34%), and transplant-related mortality (8% vs. 27%) was observed in favor of TBI–CY. In MVA, BU–CY was associated with higher relapse rates and lower survival. A subsequent update with a median follow-up of 10.8 years continued to demonstrate an advantage to TBI–CY [90].

Dusenbery et al. [66] also observed a possible advantage to TBI–CY (120 mg/kg) compared with BU (16 mg/kg)–CY (200 mg/kg) in patients with AML. For patients in first complete remission there was no difference in estimated 2-year disease-free survival. However, for patients beyond first complete remission, a trend towards improved disease-free survival was observed with TBI–CY (42% vs. 9%, $p = 0.06$). Acute toxicities and IP incidence were similar for the two regimens. None of the 18 TBI–CY patients developed SOS, compared with 3 of 17 receiving BU–CY.

The Nordic Bone Marrow Transplantation Group also demonstrated an advantage for TBI–CY over BU–CY, especially in patients with advanced disease [91,92]. Patients with AML, ALL, and CML in first remission, first chronic phase, and in more advanced phases were entered. There was no significant difference in 3-year disease-free or overall survival between the two arms when looking at the entire population. However, for patients with high-risk disease (beyond first remission or first chronic phase), TBI–CY compared favorably with BU–CY, resulting in a higher disease-free survival (61% vs. 18%, $p = 0.005$) and overall survival (66% vs. 21%, $p = 0.002$). In addition, TBI–CY was associated with a significantly lower incidence of SOS, obstructive bronchiolitis, hemorrhagic cystitis, seizures, and transplant-related mortality compared with BU–CY. It was concludes that TBI–CY is the treatment of choice, especially in patients with advanced disease. A later update with 5–9 years follow-up reached similar conclusions [90].

Bunin et al. [93] randomized children with AML to TBI or BU (16 mg/kg) combined with CY (120 mg/kg) and VP16 (16 mg/kg). Event-free survival at 3 years was 58% for the TBI group and 29% for the BU group ($p = 0.03$). The differences were primarily seen in those receiving HCT from unrelated donors.

Other randomized studies have not observed a significant advantage for TBI- over non-TBI-containing regimens. The Seattle group [69,94] reported comparable efficacy and non-relapse mortality between TBI–CY and BU–CY for patients with CML in chronic phase. BU–CY was better tolerated with a shorter length of hospital stay and lower incidence of acute GVHD. A multi-institution randomized study from France also compared TBI–CY with BU–CY in patients with CML in chronic phase [95], and observed comparable efficacy and transplant-related mortality between the two arms. Finally, a randomized trial performed by the Southwest Oncology Group compared TBI–VP16 with BU–CY and found no difference in efficacy in patients with AML, ALL, and CML beyond first complete remission or chronic phase.

Hartman et al. [96] performed a meta-analysis of five published randomized trials [69,89,91,95,97]. Survival and disease-free survival were better with TBI-based regimens compared to BU–CY but the differences were not statistically significant. A significantly greater incidence of SOS was observed with the BU–CY regimens. It was concluded that TBI regimens were at least as good as BU–CY regimens. Recently, Gupta et al. [98] performed a meta-analysis of seven randomized HCT trials involving 730 patients with leukemia randomized between BU–CY and TBI–CY. TBI–CY was associated with a modest but non-significant reduction in all cause mortality and relapse rates.

Socié et al. [68] analyzed the long-term outcome of 316 patients with CML and 172 patients with AML originally entered in four of the randomized trials described above [69,89,91,95]. Mean follow-up on the study was over 7 years. For patients with CML, there was no significant difference in 10-year overall survival or disease free-survival. For patients with AML, a trend favoring TBI regimens was observed with projected 10-year overall survival (63% vs. 51%, $p = 0.068$) and disease free survival (57% v . 47%, $p = 0.051$). Disease-free survival rates were similar if analysis was limited to AML in first remission. Late complications were similar for the two regimens, with the exceptions of a higher incidence of cataracts with TBI–CY and permanent alopecia with BU–CY.

Multiple non-randomized studies in acute and chronic leukemia have also compared TBI and non-TBI regimens, with several trials demonstrating superior efficacy with TBI regimens. Table 22.2 summarizes results from selected trials.

A limited number of studies have also compared TBI and non-TBI high-dose regimens in patients with multiple myeloma and reported no advantage to TBI [64,99]. The French Myeloma Intergroup performed a prospective randomized trial [64]. Patients with newly diagnosed multiple myeloma were randomized after VAD chemotherapy to 8 Gy TBI (2 Gy QD) and MEL (140 mg/m^2) versus MEL (200 mg/m^2). Median duration event-free survival was similar (21 vs. 20.5 months). In an analysis of the Spanish Registry for Transplantation in Multiple Myeloma [99], similar efficacy and treatment-related mortality (TRM) rates were observed for the three most common regimens used: TBI (8–12.5 Gy)/MEL (140 mg/m^2), MEL alone (200 mg/m^2), and BU (12 mg/kg)–MEL (140 mg/m^2).

In summary, several reports, including at least four randomized studies, demonstrate or suggest increased efficacy and/or decreased toxicity with TBI-containing compared with non-TBI-containing high-dose conditioning regimens, usually BU–CY, particularly in patients with acute leukemia. Most of these studies were carried out prior to patient-specific dosing of BU. Other studies demonstrate comparability between the two approaches. With respect to toxicity and treatment-related mortality rates, high-dose chemotherapy alone regimens, such as BU–CY, offer no clear advantage over TBI regimens and can be associated with a higher rate of SOS, seizures, obstructive bronchiolitis, and hemorrhagic cystitis [89,91].

TBI and reduced-intensity conditioning (RIC) regimens

Older patients or patients with comorbidities are often not able to tolerate standard myeloablative, full-intensity TBI-containing regimens. In some centers, full-intensity TBI-containing regimens are limited to patients younger than approximately 50–55 years of age. As a result, non-myeloablative and RIC regimens are being actively investigated. These regimens are usually associated with fewer acute toxicities, and are primarily used as a method of immunosuppression to allow engraftment of donor cells and the subsequent graft-versus-tumor (GVT) effects.

Both TBI-containing and non-TBI-containing regimens are being investigated. Low to intermediate TBI doses have been used. McSweeney et al. [107], using 2 Gy TBI combined with cyclosporine and mycophenolate mofetil in 45 patients, reported reduced regimen-related toxicities compared with standard high-dose regimens, a survival rate of 66.7%, and non-relapse mortality of 6.7%. However, non-fatal graft rejection was seen in 20%. As a result, the purine analog fludarabine (FLU) was added to the regimen to

increase immunosuppression and significantly reduced the rate of graft rejection [108].

Sorror et al. [109] retrospectively compared myeloablative regimens with RIC regimens (TBI 2 Gy with or without FLU) in chronic lymphoid leukemia (CLL) and lymphoma and found lower non-relapse mortality and higher overall survival rates with RIC regimens in patients with comorbidities. In patients without comorbidities, non-relapse mortality rates and overall survival rates were comparable between RIC and myeloablative regimens.

A large, multi-center, retrospective analysis of 834 patients who received related or unrelated donor transplantation following 2 Gy TBI alone or with FLU reported a 3-year relapse incidence of 25, 40, and 57% for low-, standard-, and high-risk groups, respectively [110]. It was concluded that this regimen was best for patients with low tumor burden and slow-growing tumors. Patients with high-risk disease and greater tumor burden may benefit from cytoreductive therapy before undergoing this RIC regimen.

Intermediate TBI doses of 4–9 Gy have also been evaluated as part of reduced-intensity regimens with reported success [111–115]. For example, Russell et al. [116], in a retrospective analysis, compared outcomes in AML patients between FLU, IV BU, and TBI 400 cGy (200 cGy/day × 2) (90 patients) and FLU–BU alone (89 patients). The addition of TBI resulted in a decrease in relapse rate and an increase in disease-free survival and overall survival rates, with the difference reaching statistical significance for the high-risk group. Non-relapse mortality was the same between groups.

Belkacemi et al. [117] retrospectively analyzed the European Group for Blood and Marrow Transplantation (EBMT) experience of 130 patients administered reduced-intensity regimens. A TBI dose of 2 Gy was administered in 78% and 4–6 Gy in 22%. The median dose rate was 14.3 cGy/min (range 6–16.4 cGy/min). TBI parameters did not have a statistically significant impact on outcome, possibly owing to the small number of patients in each subset. TRM incidence was 43% for dose rates ≥14.3 cGy/min and 29% for dose rates <14.3 cGy/min ($p = 0.09$).

The group at the M.D. Anderson Hospital in Houston combined 9 Gy TBI (3 Gy QD) with a reduced-intensity regimen of FLU (120 mg/m^2) and MEL (140 mg/m^2) in 29 patients with advanced pediatric hematologic malignancies [114]. The TBI dose used is close to that used in some high-dose regimens [27] and therefore begins to blur the distinction between myeloablative and reduced-intensity regimens. However, assuming an α/β ratio of 2.8 Gy based on lung toxicity [42], this regimen is the biologic equivalent of only 10.9 Gy when compared with TBI schedules delivered at 2 Gy per fraction, which usually go to a total dose of 12–16 Gy. Grade 1–2 oral mucositis and diarrhea were the most common toxicities. Although 21 donors were unrelated, only one patient had graft failure. The TRM rate was 24%. It was concluded that this regimen was fairly well tolerated, but also pointed out that the same regimen was not tolerated in adults in a separate trial forcing study closure.

In summary, low to intermediate doses of TBI have been successfully integrated into RIC regimens with encouraging results and continue to be actively investigated, especially in older patients and those with comorbidities unable to tolerate myeloablative regimens. The optimal TBI dose in RIC regimens remains to be determined. Compared with myeloablative regimens, RIC regimens result in lower TRM rates, but higher relapse rates, particularly for patients with high-risk disease. Efforts to improve results using higher TBI doses will prove challenging in this patient population owing to increased treatment-related morbidities. More targeted forms of radiotherapy delivery associated with lower toxicity are now being investigated as part of RIC regimens [6,118].

Total lymphoid irradiation (TLI)

TLI has been used instead of TBI for patients undergoing allogeneic HCT with malignant and non-malignant conditions such as aplastic anemia and thalassemia [119–121]. TLI provides the needed immunosuppression with reduced dose to critical organs compared with TBI. Mantle and inverted Y fields, which cover the major central lymphoid regions, are often utilized. As with TBI, TLI is often combined with chemotherapy such as CY or BU–CY. TLI (approximately 6–8 Gy) has also been combined with standard doses of TBI in an effort to increase immunosuppression and engraftment further, especially in patients receiving T-cell-depleted donor marrow [122,123].

The group at Stanford University has evaluated the use of fractionated non-myeloablative TLI and antithymocyte globulin (ATG) as an immunomodulatory strategy to reduce the incidence of acute GVHD and promote tolerance in patients receiving allografts [124,125]. This novel approach takes advantage of the immune system's regulatory T cells and the relative radioresistance of regulatory natural killer T (NKT) cells compared with conventional T cells [126]. NKT cells prevent acute GVHD by inhibiting proliferation and cytokine secretion of CD4$^+$ and CD8$^+$ donor T cells without affecting GVT activity [127]. Secretion of interleukin-4 by NKT cells appears to be involved [128]. Initial preclinical studies in mice demonstrated that pre-transplant non-myeloablative doses of TLI resulted in chimerism and tolerance to allogeneic bone marrow and skin grafts without the development of GVHD [129]. In larger animal models, prolonged tolerance to mismatched heart allografts was observed when lower doses of pre-transplant TLI combined with antithymocyte serum was administered [130]. TLI and antithymocyte serum delivered in the post-transplant setting also resulted in donor-specific tolerance of mismatched heart transplants if same donor bone marrow was also infused immediately after TLI [131].

TLI strategies developed in preclinical models have demonstrated promise in the clinic. In an initial report, 37 patients with lymphoid malignancies or acute leukemia received 8 Gy fractionated TLI (80 cGy × 10 fractions over 11 days) and ATG followed by HLA-matched mononuclear cells from related and unrelated donors. Only 2 of 37 had acute GVHD. Seven of 33 had extensive chronic GVHD. Of 18 patients with lymphoid malignancies and measurable disease at the time of transplant, 12 achieved complete remission without acute GVHD. An increase in the median percentage of NKT cells and a marked reduction in the response to alloantigenic stimulation of donor CD4$^+$ T cells were also observed. In an update of 111 patients (64 lymphoid and 47 myeloid), acute GVHD (grades 2–4) were 2% and 10% in patients receiving related and unrelated donor grafts, respectively [132]. Cumulative chronic GVHD was 27%. About 69% of patients were taken off immunosuppressive drugs (1–7 years). Consistent with observations from preclinical studies, there was a median decrease of CD3$^+$, CD4$^+$, and CD8$^+$ T cells of 191-, 180-, and 268-fold, respectively, but only an 8.6 - fold decrease in NKT cells. Overall survival and event-free survival at 36 months were 60% and 40%, respectively. Outcomes were best in patients with NHL in complete remission (CR) or partial remission (PR), AML in CR1 or CR2, and those who achieved complete donor chimerism.

Tolerance induction after TLI and ATG has also been demonstrated in kidney transplant recipients. Sixteen patients were conditioned with TLI (80 or 120 cGy × 10 fractions) and ATG in the first 10 days after kidney transplantation followed by infusion of donor CD34$^+$ hematopoietic progenitor cells and 1×10^6/kg T cells on day 11. Fifteen patients developed chimerism without GVHD and eight were withdrawn from antirejection immunosuppressive drugs for 1–3 years. Higher ratios of CD4$^+$CD25$^+$ regulatory T cells and NKT cells compared with conventional naïve CD4$^+$ cells were observed in all patients [133].

Involved field radiotherapy

Involved field radiotherapy (IFRT) to sites of initial involvement is often utilized in patients with Hodgkin and non-Hodgkin lymphoma undergoing HCT. This is based on the fact that locoregional disease, particularly if bulky on initial presentation, can often be a site of relapse after systemic therapies. Most patients who relapse after high-dose regimens recur in sites of initial disease [134–136]. IFRT to involved sites will reduce relapse rates. For example, Poen et al. [134] reported on 100 patients with Hodgkin disease transplanted at Stanford. Of the 32 patients who relapsed, 22 relapsed at sites involved prior to transplant. In the 49 patients who received IFRT, 3-year freedom from relapse was 100% compared with 67% ($p = 0.04$) for the 13 who did not receive IFRT. Moskowitz et al. [137] combined 18 Gy IFRT and 18 Gy TLI prior to high-dose chemotherapy and autologous HCT in patients with refractory of relapsed Hodgkin disease. Event-free survival was 68% and only 18% relapsed in previously irradiated areas. Similar findings were seen in patients with NHL undergoing HCT [136]. Hoppe et al. [138] delivered IFRT prior to autologous HCT in 164 patients with relapsed or refractory diffuse large-cell lymphoma. Of 67 patients who relapsed, only 10 relapsed completely in the IFRT field. The group at the University of Rochester transplanted 164 patients with refractory or recurrent large B-cell NHL, of whom 85 received IFRT after autologous HCT, and noted a 10% reduction in local failure rate and a significant increase in overall and disease-specific survival in the IFRT group.

Other studies have cautioned against combining TBI with IFRT to the mediastinum and thorax owing to an increased risk of IP [139]. Friedberg et al. [140], in a large retrospective analysis of 552 patients with NHL undergoing TBI and high-dose chemotherapy conditioning regimens prior to autologous HCT, compared outcomes between the 152 patients who received IFRT prior to conditioning regimen with the 400 patients who did not. IFRT resulted in a significantly higher rate of secondary myelodysplasia (12.5% vs. 5.8%) and, in those receiving IFRT to the mediastinum and axilla, a significant increase in late respiratory death (25% vs. 5%). There was no difference in progression-free survival or acute treatment-related mortality with IFRT. However, Song et al. [141], in a phase I study of 21 patients with lymphoma, observed no significant pulmonary toxicity with IFRT given 1 week prior to 12 Gy TBI. Others have successfully combined TLI with TBI with no reported significant additional toxicity [122,123].

Targeted total body irradiation and future directions

A dose–response relationship has long been recognized for many types of hematologic malignancies [142–144]. TBI dose escalation in patients with AML and CML has resulted in lower relapse rates [25], but these were accompanied by an increase in treatment-related complications resulting in no change in overall survival [26,145]. New strategies are needed to allow further dose escalation without associated increases in short- and long-term side effects. Various approaches are currently being actively explored to deliver a more targeted form of TBI, one that would preferentially deposit higher doses to areas of greatest tumor burden to maximize disease control, while simultaneously reducing the dose to critical normal organs to reduce toxicities.

Biologically guided systemic radiotherapy, using radiolabeled antibodies or bone-seeking radiopharmaceuticals such as ^{166}Ho-DOTMP, are currently undergoing evaluation as part of HCT conditioning regimens. This area is covered in more detail in Chapter 24 and has been reviewed elsewhere.

Recent technologic advances in radiotherapy systems now allow for the delivery of a more targeted form of TBI. The TomoTherapy HiArt System® was the first system to be used to deliver targeted TBI. Tomotherapy uses a 6 MV linear accelerator mounted on a computed tomography (CT) ring gantry that rotates around the patient as the patient translates through the ring. The maximum target size is approximately 60 cm in width by approximately 160 cm in length [146]. This allows for the delivery of conforming dose distributions to large, complex target shapes while simultaneously reducing the dose to critical normal organs [147], making it suited for the delivery of conformal targeted TBI. More recently, other groups have reported on the potential use of other volumetric arc-based image-guided IMRT systems to deliver targeted TBI [148–150]. This approach has also been referred to as total marrow irradiation (TMI) or total marrow and lymphoid irradiation (TMLI).

The group at City of Hope Cancer Center transplanted the first patients utilizing tomotherapy to deliver 10-17 Gy in patients with multiple myeloma and acute leukemia [2–7,151–154]. Figure 22.4 shows the typical conformal dose distribution pattern that is achieved to the designated target structure, with simultaneous reduction of dose to critical organs. Table 22.3 compares the median doses for various normal organs delivered through standard TBI to 12 Gy with lung shielding versus TMI to 12 Gy to the skeletal bone. Figure 22.5 shows normal organ dose–volume histogram plots for standard TBI versus TMI in the same patient. Depending on organ site, a reduction in median organ doses of approximately 15–80% and volume of organ receiving full dose compared with standard TBI has been reported, predicting reduced short- and long-term toxicities. The system can also be used to reduce differentially the radiation dose to organs or any other user-defined avoidance structure, depending on the radiosensitivity of the organ, and also to increase the dose to a particular target region depending on the tumor burden and clinical situation.

A phase I trial evaluated TMI in patients with Durie–Salmon Stage I–III multiple myeloma [2,5,155] responding after first-line therapy. Patients underwent tandem autologous HCT, with MEL (200 mg/m^2) followed by TMI. The TMI dose was escalated from 10 to 18 Gy at 2 Gy BID. The TMI target structure was bone (Figure 22.4). This trial allowed the evaluation of baseline toxicities associated with TMI without concurrent chemotherapy. Dose-limiting toxicities were not observed until a TMI dose of 18 Gy (one patient with reversible grade 3 pneumonitis, congestive heart failure, and enteritis and one patient with grade 3 hypotension), establishing the MTD at 16 Gy.

A subsequent pilot trial evaluated TMLI 12 Gy (1.5 Gy BID) combined with the reduced-intensity regimen of FLU (25 mg/m^2/d × 5 days) and MEL (140 mg/m^2) followed by allogeneic HCT in patients with advanced hematologic malignancies (primarily AML) who were over age 50 years or with comorbidities making them

Stomach	4.6	11.5	0.40
Thyroid	4.4	12.6	0.35

Standard TBI utilized 10 MV photons to deliver 12 Gy; 50% attenuation blocks were used to shield the lungs. Electrons were used to deliver 6 Gy to the rib cage underlying the lung blocks. Data are averages of comparison plans from six patients [3].

ineligible for standard TBI myeloablative regimens [6]. The treatment-related mortality rate at 1 year was 19%, which compared favorably with the 30-40% rates reported for FLU and MEL alone in a similar patient population [156–159].

Phase I trials have also evaluated TMLI with higher intensity chemotherapy conditioning regimens. Twelve patients with high-risk (relapse or induction failure) acute leukemia less than age 55 years and not eligible for other intent-to-cure standard HCT regimens underwent allogeneic HCT with a conditioning regimen of TMLI, etoposide (VP16, 60 mg/kg), and CY (100 mg/kg). The TMI dose ranged from 12 to 15 Gy (1.5 Gy BID). Nine patients had persistent marrow blasts (10–98%) and five had circulating blasts (24–85%). Eleven of 12 achieved complete remission at day 30. The non-relapse mortality (NRM) cumulative incidence at day 100 was 8% [4]. Dose escalation on this trial continues. A phase I trial of TMLI with BU and VP16 in 20 patients with AML in relapse or with induction failure demonstrated that TMLI dose escalation was not feasible, with dose-limiting toxicities seen at 13.5 Gy [4]. Table 22.4 summarizes the toxicities of TMI trials at City of Hope Cancer Center.

Other groups have also evaluated TMI and TMLI containing regimens. Hui and colleagues at the University of Minnesota [160] reported on the first patient treated as part of a phase I autologous HCT trial in Ewing sarcoma using TMI to 6 Gy (2 Gy per day), followed by BU (targeted, 4 mg/kg days –8 to –6), MEL (50 mg/m^2 days –5 and –4), and thioTEPA (250 mg/m^2 days –3 and –2). The regimen was well tolerated with only nausea and vomiting observed. Sheung et al. [161] reported on three patients conditioned with 8 Gy TMI at 2 Gy per day (days –6 to –3) combined with MEL at 140 m/m^2 (day –2) prior to autologous HCT and observed only a single event of grade 3 toxicity (mucositis). Corvo et al. [162] demonstrated the feasibility of adding a 2 Gy TMI boost to bone marrow and spleen after standard TBI 12 Gy and CY in patients with AML and ALL undergoing allogeneic HCT. Other centers in Europe, North America, and Asia have also initiated trials but the early experience to date remains unpublished.

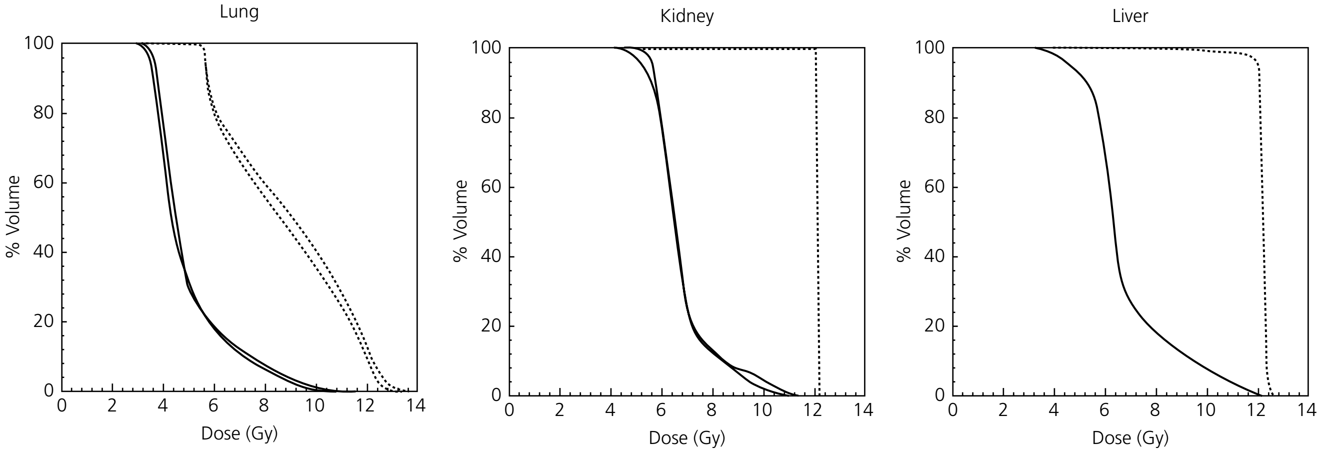

Figure 22.5 Comparison of dose–volume histogram (DVH) plots for lungs, liver, and kidneys with TMI versus standard TBI to 12 Gy. TBI and TMI plans were performed on the same patient data set. Standard TBI utilized 10 MV photons to deliver 12 Gy; 50% attenuation blocks were used to shield the lungs. Electrons were used to deliver 6 Gy to the rib cage underlying the lung blocks. With standard TBI (dashed lines) close to 100% of the liver and kidneys receive the full dose of 12 Gy. Lung shielding results in reduced doses to the lung, although 100% of the lung still receives approximately 6 Gy. With TMI, the DVH plots (solid lines) demonstrate reduced doses to a large percentage of each organ compared with TBI.

Table 22.4 Summary of toxicities observed on TMI trials at City of Hope Cancer Center

Parameter	CY–VP16–TMI [4]	BU–VP16–TMI [4]	FLU–MEL–TMI [4,6]	MEL → TMI [4,5]
TMI dose (Gy)	12.0, 13.5, or 15.0	12.0 or 13.5	12	10, 12, 14, 16, or 18
Target organs	Bone, major lymph node chains, spleen, liver, brain, testes	Bone, major lymph node chains, spleen, liver, brain, testes	Bone, major lymph node chains, spleen If ALL: brain, testes	Bone
Chemotherapy	Cyclophosphamide (CY) + etoposide (VP16)	Busulfan (BU) + etoposide (VP16)	Fludarabine (FLU) + melphalan (MEL)	Melphalan (MEL)
Type of transplant	Allogeneic	Allogeneic	Allogeneic	Tandem autologous
No. of patients	12	20	47	31
Diagnosis	AML, ALL, mixed lineage	AML	AML, ALL, NHL, MDS, CML	MM
Median age (range) (years)	33 (21–54)	41 (23–52)	55 (12–68)	53 (35–66)
Day 30: grade 3 toxicities (NCI CTC)	Nausea 4 (33%) (3 at 15 Gy) Vomiting 1 (8%) (1 at 15 Gy) Mucositis 7 (58%) (6 at 15 Gy) Esophagitis 0 Diarrhea 0	Nausea 9 (45%) Vomiting 1 (5%) Mucositis 17 (85%) Esophagitis 1 (5%) Diarrhea 3 (15%)	Nausea 26 (55%) Vomiting 13 (28%) Mucositis 28 (60%) Esophagitis 2 (4%) Diarrhea 27 (57%)	Nausea 3 (10%) (2 at 18 Gy, 1 at 16 Gy) Vomiting 0 Mucositis 0 Esophagitis 0 Diarrhea 1 (3%) (1 at 18 Gy) Pulmonary 1 (6%) at 18 Gy DLT Hypotension 1 (6%) at 18 Gy DLT
Day 30: NCI CTC v3 grade 4 or Bearman grade 3 toxicities	None	Mucositis 1 (5%) at 13.5 Gy Ileus and SOS 1 (5%) at 13.5 Gy	Pulmonary 5 (11%) Renal 4 (9%) Bladder 1 (2%) CNS 1 (2%) Cardiac 2 (4%)	None
Non-relapse mortality at 100 days	1 (8%) (at 15 Gy)	4 (20%) (2 at 13.5 Gy)	7 (15%)	None

In summary, strategies to deliver a more targeted form of TBI are being actively investigated through the use of newer image-guided IMRT radiotherapy delivery systems. The potential advantages are the ability to reduce normal organ doses, reduce toxicities, and broaden the range of patients able to undergo radiation conditioning regimens, such as older patients or those with comorbidities. This approach also offers the opportunity to escalate target dose with acceptable toxicities in an effort to improve outcomes.

Key points

- TBI remains an important component of HCT conditioning regimens owing to its immunosuppressive and antitumor effects.
- Fractionated TBI is superior to single-fraction TBI schedules owing to reduced normal tissue toxicity.
- Dose-rate effects in normal tissues decrease with fractionation. Dose-rate effects are minimized with fractionated schedules.
- TBI or TLI is also an important part of many reduced-intensity regimens. Fractionated TLI demonstrates promise as a method to reduce the incidence of GVHD and induce tolerance to allografts.
- Evaluation of image-guided intensity-modulated radiotherapy delivery systems as a method to deliver a more targeted form of TBI is ongoing. This allows for the potential to dose escalate to tumor or selected target regions, with simultaneous reduction in dose to critical structures, which could improve the therapeutic index of TBI.

CHAPTER 23

Radioimmunotherapy and Hematopoietic Cell Transplantation

John M. Pagel and Ajay K. Gopal
Fred Hutchinson Cancer Research Center, University of Washington School of Medicine, Seattle Cancer Care Alliance, Seattle, WA, USA

> The odds of hitting your target go up dramatically when you aim at it.
> Anonymous

Background

For over half a century, minimal attention was paid to German pathologist Paul Ehrlich's prescient notion for utilizing target specific antisera as a form of cancer therapy [1]. While in the late 1890s Hericourt and Richet reported temporary responses in patients treated with antisera raised against human osteogenic sarcomas, and Madame Marie Curie and colleagues identified a potential role for the α particle-emitting radionuclide radium as an intravenous therapeutic [2], few other studies advanced the field of targeted radiation therapy for over 50 years. In 1949, Eisen's report of a technique for linking radioactive iodine to antibodies without impairment of antibody binding [3] paved the way for Pressman and Korngold's discovery that radioiodinated tumor-specific antibodies would preferentially accumulate in target tissues [4]. In the 1960s, Bale et al. demonstrated that ^{131}I-labeled antibodies could be effective as therapeutic agents [5]. Also in the 1960s, radioiodinated antifibrinogen was shown to provide some symptomatic improvement in a variety of tumor types [6]. In the 1970s, Ettinger et al. demonstrated significant responses in patients with hepatoma treated with ^{131}I-labeled anti-CEA or antiferritin antibodies in combination with external beam radiation and doxorubicin chemotherapy [7]. Lenhard et al. subsequently showed that ^{131}I-labeled polyclonal antiferritin antisera could produce objective remissions in patients with hepatomas and also up to 40% of patients with relapsed lymphoma [8].

In 1975, Kohler and Milstein's Nobel Prize winning work made practical the large-scale production of monoclonal antibodies (MAbs) with defined and reproducible specificity. Great excitement surrounding a new era of MAb-directed therapy ensued; however, initial studies with unlabeled MAbs did not meet the expectations of many observers. Over the past decade, two chemically conjugated MAbs, an anti-CD33 MAb chemically conjugated to the cytotoxic drug calicheamicin (gemtuzumab ozogamicin) was approved for the treatment of relapsed acute myeloid leukemia (AML), and more recently an anti-CD30 MAb drug conjugate (brentuximab vedotin) for Hodgkin lymphoma. In addition, several unconjugated MAbs have been approved as cancer therapies in the United States, with two anti-CD20 radiolabeled MAbs, [^{131}I]tositumomab and [^{90}Y]ibritumomab tiuxetan, approved. Each of these unconjugated or chemically conjugated MAbs has shown clinical promise, but most patients treated with these products as single agents subsequently relapse.

As predicted in animal studies, the limitations of unmodified MAb therapy largely result from inadequate host effector mechanisms. In the absence of robust immune effector mechanisms, MAbs bound to antigen on the target cell surface usually do not diminish cell replication and survival sufficiently to eradicate tumors. In addition, antigenic modulation (internalization or shedding) after antibody–antigen complex formation limits the availability of a stable target in many clinical settings. A third impediment to effective cell killing results from variable expression of antigenic targets, including antigen-negative variants in most tumor types. Finally, antigen penetration into large tumors is limited by the vascular supply and the kinetics of intratumoral MAb convection and diffusion.

Throughout the 1980s, interest in radioimmunotherapy (RIT) grew owing to the recognition that radioimmunoconjugates could bypass many of the limitations enumerated above. By providing the MAbs with a cytotoxic mechanism independent of the host immune response, radiolabeled antibodies (RAbs) circumvent the major obstacle to antibody-directed therapy. Furthermore, the use of radionuclides with path lengths that span several cell diameters provides a "crossfire" effect that delivers toxic radiation from the surrounding antigen-bearing cells to tumor cells that are antigen negative or that lack direct access to MAb binding.

In recognition of these advantages, initial preclinical studies with RIT sought to identify both appropriate antigen targets for optimal biodistribution and identification of the factors necessary for tumor cell destruction. These early studies elucidated a number of key principles concerning the biodistribution of RAbs. In addition, these studies documented that 4–10 times more radiation could be delivered to tumors compared with normal organs by using radioimmunoconjugates. Unfortunately, myelotoxicity frequently prevented radiation dose escalation to curative levels in early studies of RIT [9,10]. The understanding that marrow suppression was dose limiting inspired some groups to explore RIT in combination with stem-cell support.

The concept that hematopoietic stem-cell rescue could facilitate dose escalation to curative levels was supported by the work in the early 1970s of Thomas and colleagues, who first defined a role for bone marrow transplantation (BMT) in the treatment of acute leukemia. Clinical trials conducted in Seattle demonstrated the antileukemic effect of total body irradiation (TBI) in combination with high-dose chemotherapy for BMT [11]. Importantly, higher doses of TBI correlated with a reduced-risk of disease recurrence

after transplant. In two randomized trials, patients with either AML [12] or chronic myeloid leukemia (CML) [13] were given cyclophosphamide (CY) and either 12 or 15.75 Gy of TBI conditioning prior to allogeneic sibling-matched BMT. The rate of post-transplant relapse dropped from 35% to 13% in the AML population and from 30% to 7% in the CML group for those patients receiving the higher dose of TBI. These studies clearly demonstrated the potential for higher doses of radiation to generate more durable responses; however, those in the higher dose group experienced a significant increase in severe or fatal toxicities. Owing to the increased frequency of toxicity (most often radiation-induced pneumonitis, mucositis, or hepatic damage), the higher doses of TBI did not improve overall patient survival. Nonetheless, Thomas' studies demonstrated a steep dose–response curve of the leukemia to radiation and supported the need for improved methods of selectively delivering radiation to malignant cells.

With this background information, researchers in the late 1980s and 1990s finally developed effective clinical applications for Ehrlich's initial concept of "magic bullets" as a form of cancer therapy. Animal models demonstrated that marrow ablation was feasible with RAbs and that subsequent stem-cell infusion could restore marrow function reliably [14]. Non-myeloablative doses of ^{90}Y- and ^{131}I-labeled anti-CD20 MAbs consistently produced remissions in 50–80% of patients with relapsed, refractory, or transformed follicular non-Hodgkin lymphoma (NHL) and led to regulatory approval of both [^{90}Y]ibritumomab tiuxetan (Zevalin™) in 2002 and [^{131}I]tositumomab (Bexxar™) in 2003 by the US Food and Drug Administration (FDA). Despite such high overall response rates, however, most patients treated with standard non-myeloablative doses of radiolabeled anti-CD20 MAbs eventually relapse, indicating the desirability of further dose escalation.

Despite the enormous potential for targeted therapy, problems were identified soon after the early clinical RIT trials were completed. Initially, it was thought that any tumor could be targeted efficiently with MAbs. However, the long circulatory half-life of the blood-borne RAbs causes prolonged high background activity levels, leading to non-specific normal organ exposure to radiation. After the detection of peptide receptor expression by tumors, peptide analogs began to be investigated for specific tumor targeting. Peptides used for tumor targeting show several advantages over antibodies; peptides are small and show rapid diffusion into (target) tissues resulting in rapid pharmacokinetics. Their fast blood clearance could lead to high tumor-to-background ratios shortly after administration of the radiopeptide.

Considerable expansion has been accomplished with use of pretargeted RIT and other methods to enhance tumor-to-normal organ tissue ratios, such as the use of α-emitting radionuclides. This chapter focuses on these clinical therapeutic aspects of targeted radionuclides for diagnosis and therapy of tumors. The current state of clinical use of RAbs and radiopeptides, and the state of development of new compounds and future innovations are reviewed. Discussion of preclinical studies is limited to those that offer insights into future directions for clinical study. The radioisotopes appropriate for diagnosis and therapy and the radiolabeling methods that are currently in use are described.

Components of RIT

Specific antigen targeting with RAbs is designed to produce a biodistribution profile favoring radiation delivery to malignant cells; however, a portion of the radioimmunoconjugate remains unbound in the circulation and contributes to non-specific irradiation of normal tissues. The relative exposure of target and non-target tissues can be non-invasively estimated via imaging. The term biodistribution describes measured values of the relative levels of radionuclide throughout the body. In preclinical research models, biodistributions can be accurately measured by tissue sampling at serial time points after infusion of the radioimmunoconjugate, with quantitative measurements of the radionuclide content per gram of tissue [9]. In large animal models and human subjects, biodistributions are usually determined using radionuclides that possess a γ emission profile suitable for serial quantitative γ camera imaging. Regions of interest including the liver, lung, spleen, kidney, and marrow can be serially imaged and activity curves representing counts per pixel generated. These data are calibrated using direct measurements of radionuclides in accessible tissues such as blood, marrow, and lymph nodes, thus allowing the construction of time–activity curves and calculation of estimated absorbed radiation doses in tumor sites and normal organs (radiation dosimetry). These calculations have been typically based on methods established by the Society of Nuclear Medicine Special Committee on Medical Internal Radiation Dose (MIRD) [15–17]. Factors that influence the biodistribution of RAbs have been delineated through both preclinical animal studies and patient trials (Table 23.1).

Table 23.1 Factors that influence biodistribution of radiolabeled antibodies.

I. *Nature of the targeted antigen*

  c. Route

IV. *Labeling procedure*
  a. Choice of radionuclide
  b. Labeling chemistry

Target antigen selection

Appropriate target antigen selection is crucial if a favorable biodistribution of RAbs is to be achieved. Ideally, the target antigen will be expressed homogeneously on the cell surface of all target tumor cells at a high surface density and will not be expressed on any normal cells. Unfortunately, such tumor-specific cell-surface antigens are rare, and in practice the selection of lineage-specific hematopoietic antigens (e.g., CD20, CD45) has proven to be highly successful in the setting of hematopoietic stem-cell transplantation (HCT) where marrow rescue and hematopoietic reconstitution are anticipated. In fact, employing these more widely distributed lineage-specific antigenic targets offers an increased likelihood of eliminating both antigen-negative tumor cell variants and rare diseased cells within a remission marrow due to radioactive crossfire effects from adjacent antigen-positive hematopoietic cells [18].

Antigen density correlates directly with accumulation of MAbs at tumor sites [19]. When the number of antigenic sites is less than 10,000, target saturation occurs at a relatively low MAb dose. This is a significant limitation, as each MAb molecule can be labeled with only a limited amount of radionuclide before immunoreactivity is impaired. Low antigen density theoretically poses less of a problem for studies involving α particles, which require only a single DNA "hit" to kill a cell. However, for the more commonly used β-emitting radionuclides, multiple hits are required to induce irreparable DNA strand breaks resulting in cell death. A second factor in antigen selection is the extent to which the receptor is internalized following binding. Whereas some antigens remain stably on the cell surface after antibody binding, others are rapidly endocytosed and are transported to lysosomes for proteolytic degradation [20,21]. After this process of internalization, the receptor density may remain low for several days. One of the best studied radionuclides in RIT, ^{131}I, is not optimal for targeting internalizing receptors because rapid lysosomal metabolism of the conjugate leads to release of free [^{131}I]- and [^{131}I]monoiodotyrosine from cells [22,23]. This degradation significantly reduces the residence time of the radionuclide in tumor sites and therefore decreases the dose of cytotoxic radiation delivered to the malignant cells. When internalized antibodies are labeled with ^{111}In or ^{90}Y, however, low molecular weight cationic metabolites remain trapped within the lysosomes and their impact is not significantly diminished [24]. Surface antigens that are not internalized following antigen–immunoconjugate complex formation exhibit minimal variation in cellular retention of ^{131}I, ^{111}In, and ^{90}Y [24,25].

CD20 is one of the best studied and most frequently targeted receptors for B-cell neoplasms and possesses many of the favorable attributes noted above. It has a high density of expression on more than 90% of B-cell tumors and most investigators have demonstrated it to be minimally internalized and minimally shed from the cell surface of most B-cell malignancies. Potential limitations of anti-CD20 RIT have emerged, however, including inferior response rates in patients with B-cell depletion and higher serum levels of the unconjugated anti-CD20 MAb rituximab [26]. where preclinical data indicate that CD20 blocking may impair the ability to target CD20 with RIT [27]. One alternative is to circumvent the potential of CD20 blocking and the exclusion of CD20-negative NHL histologies by targeting the pan-hematopoietic antigen CD45 [27]. CD45, also known as leukocyte common antigen, is a cell-surface glycoprotein (size, 180–220 kDa) with tyrosine phosphatase activity [28]. Absent on non-hematopoietic cells, almost all hematopoietic cell lineages express CD45, except mature thrombocytes, mature erythrocytes, and some of their progenitors. Most hematologic malignancies, including 85–90% of acute lymphoid and myeloid leukemias, express CD45 [29–31]. This antigen is expressed in a relatively high copy number (200,000 binding sites per cell) and is not appreciably internalized or shed after ligand binding [24,32]. CD45 exists in several isoforms; however, although isoform-specific MAbs have been developed and investigated for immunotherapy, the CD45-targeting MAbs used so far for RIT are pan-specific.

Similarly to CD45, CD66 antigens are neither internalized nor shed [33]. They are expressed on members of the carcinoembryonic-antigen-related cell-adhesion molecule (CEACAM) family of proteins that play a role in various intercellular-adhesion and intracellular signaling-mediated effects involved in cellular growth and differentiation [34]. Some of these glycoproteins, namely CD66a (CEACAM1, biliary glycoprotein), CD66b (CEACAM8, CGM6), CD66c (CEACAM6, non-specific cross-reacting antigen), and CD66d (CEACAM3, CGM1), are expressed on hematopoietic cells but can also be found on epithelial or endothelial cells. CD66 antigens are found in myeloid cells from the late myeloblast or early promyelocyte stage and reach the highest levels in myelocytes and metamyelocytes, whereas early myeloid progenitors or multipotent progenitors do not express CD66 antigens [35–37]. CD66 antigens are only occasionally found on AML cells, but many B-cell acute lymphoblastic leukemias and some cases of lymphoid blast crisis CML express these antigens [36,38]. Studies with a CD66c-specific MAb suggested restriction primarily to CD10-positive early B-cell acute lymphoblastic leukemia (ALL) [39]. However, many anti-CD66 MAbs recognize several CD66 antigens; for example, BW 250/183, the most widely used MAb for CD66-targeted RIT, recognizes CD66a, -b, and -c [40]. Therefore, although the exact expression patterns may differ between the individual CD66 antigens, these patterns may be currently of limited significance for radioimmunotherapeutic approaches [34,39].

Since CD33 and CD45 are expressed by both normal and malignant cells, MAbs targeting these antigens can deliver radiation to marrow, spleen, and lymph nodes in patients with measurable disease and also in patients in remission. Malignant cells that do not express these antigens may be killed if they are surrounded predominantly by non-malignant hematopoietic cells because of the bystander effect. This bystander effect is particularly important for RIT of myeloid leukemia using CD66, as these antigens are commonly not expressed by the malignant clone.

In addition to CD33, CD45, and CD66, a number of other antigens have been used in clinical studies of RIT of leukemia, including HLA-DR, CD5, CD20, CD22, CD25, and CD37. For example, CD5 is a surface antigen present on T cells, a subset of B cells, and subsets of chronic lymphoid leukemia (CLL) cells [41]. CD25 (interleukin-2 receptor, α subunit) is felt to be an attractive target for RIT as it is only weakly expressed in some normal tissues, including epithelial tissues and lymphocyte subsets, but is found on malignant cells in several diseases, including adult T-cell leukemia, cutaneous T-cell lymphoma, anaplastic large-cell lymphoma, hairy cell B-cell leukemia, and the Reed–Sternberg and associated polyclonal T cells in Hodgkin disease, in addition to some AML [42].

Antibody selection

MAb specificity and binding kinetics also play an important role in optimizing the biodistribution of RAbs. MAbs with a low immunoreactivity do not accumulate at sufficient levels in target tissues and result in a relatively non-specific pattern of distribution. In the setting of HCT, accumulation at high levels in the marrow is anticipated and reversible, hence non-specific cross-reactivity in radiosensitive organs such as lung and liver are frequently dose limiting. In contrast, cross-reactivity with marrow elements is of great significance in the non-HCT setting where myelosuppression frequently limits dose escalation. Another factor in MAb selection relates to stability, since MAbs susceptible to damage or agglutination during the labeling process often accumulate in the liver. In early studies, MAbs with high avidity were presumed to be optimal for RIT [43]; however, subsequent findings have suggested that very high avidity may promote heterogeneity of MAb deposition through enhanced uptake at the most peripheral perivascular target sites. This so-called binding site barrier [44] was subsequently demonstrated in a non-human primate study employing two different CD45 MAbs in which the MAb with slightly higher avidity preferentially localized to the most easily accessible antigen-positive cells and was rapidly cleared from the circulation (~2 hours) [45]. Meanwhile the MAb with slightly lower avidity stayed in the circulation longer and demonstrated superior uptake in the lymph nodes, a less accessible target site.

The use of antibody fragments to improve the rate of penetration and overall distribution of RAbs has been investigated. These smaller fragments produced by enzyme digestion of intact MAbs (Fab, 50 kDa; $F[ab']_2$ 100 kDa) or through cloning and expression of the Fv portions of the immunoglobulin light and heavy chains in *Escherichia coli* (scFv, 25 kDa) permit more rapid diffusion into tumor sites [46,47]; however, their small size results in rapid clearance and short retention times compared with intact immunoglobulin G (IgG) antibody [48–52].

Owing to the murine origin of most MAbs used for RIT, patients may develop a humoral immune response with formation of a neutralizing human antimouse antibody (HAMA). The presence of HAMAs can result in an altered RAb biodistribution due to rapid circulatory clearance and increased hepatic uptake of the resultant immune complexes. HAMAs may also compromise diagnostic in vitro immunoassays employing analytes containing murine immunoglobulins (e.g., hormone assays) [53]. HAMAs usually develop 4–8 weeks after first exposure. HAMAs have posed less of a problem for patients with hematolymphoid malignancies in whom the capacity to mount a robust immune response to neo-antigens is usually impaired. Moreover, HAMA-related complications are generally relevant only for patients treated with repeated doses of murine MAbs, hence HCT patients are at significantly lower risk because they complete RIT conditioning over a short time period. The HAMA response can be limited by the use of immunosuppressive agents (e.g., cyclosporine), development of humanized or chimeric molecules, single infusions, and the use of less immunogenic MAb fragments.

Antibody pharmacology

Studies in murine models, non-human primates, and human subjects have documented the importance of appropriate antibody dosing to achieve optimal RAb biodistributions [9,10,21,54]. Each MAb possesses a specific dose range sufficient for achieving antigen saturation. Low doses result in relatively poor accretion of RAbs in lymph nodes and tumor masses, resulting in unfavorable tumor-to-normal organ ratios. Excessive doses beyond target saturation simply increase the fraction of injected radionuclide that persists in the circulation and non-specifically irradiates normal tissues. The precise MAb dose that delivers the optimal radiation exposure to tumor sites and limits exposure to normal organs in a given clinical scenario also depends on the burden of antigen-expressing cells (tumor load) and the presence of persistent prior antibody (e.g., rituximab) that may compete for target antigens and Fc receptors [27].

In the HCT setting, RAb infusions usually involve a trace labeled test dose (or "dosimetric infusion") to assess the individualized biodistribution, followed by a therapeutic infusion. The rate of infusion is determined by patient tolerance, with fever, dyspnea, and hypotension limiting rapid infusion rates of some MAbs. Based on the presence of a large number of antigen-expressing cells in the circulation of leukemia patients, alternative infusion schedules have been investigated. Animal studies have suggested that a small dose of unlabeled antibody to clear circulating cells expressing the target antigen may lead to an improved biodistribution of the subsequently administered labeled dose [55]. Preliminary patient trials have been inconsistent in this regard, with one group reporting no benefit of this approach in an anti-CD45 MAb (BC8; murine IgG1) model [56] and another demonstrating a significant enhancement in bone marrow uptake when a low-dose of unlabeled anti-CD45 MAb (YAML568; rat IgG2a) is injected prior to therapy [57].

To allow for re-expression of an internalizing antigenic target (CD33), a model in which three divided doses delivered at 48–72 hour intervals has been studied in patients with AML [58]. Fractionation has also been evaluated for B-cell NHL with a non-internalizing target (CD20) to allow a delivery of a higher total absorbed dose [59].

Table 23.2 Radionuclides for radioimmunotherapy

Radionuclide	Particles	$T_{1/2}$	Median energy (MeV)	Comments
Beta-emitters				
Iodine-131	β, γ	8.1 days	0.66 β	Well-defined chemistry, inexpensive, dehalogenation a problem, long $T_{1/2}$
Yttrium-90	β	2.7 days	2.3 β	High energy, no γ, accumulates in liver and bone
Lutetium-177	β, γ	6.7 days	0.50 β	Long $T_{1/2}$, low energy, stable when internalized, lower γ than ^{131}I
Rhenium-188	β, γ	17 h	4.4 β	Limited access
Rhenium-186	β, γ	89 h	1.8 β	
Copper-67	β, γ	2.6 days	0.57 β	Lower γ than ^{131}I, can image with PET, limited access
Alpha-emitters				
Bismuth-213	1α, 2β	46 min	5.84 α	High energy, short path length, very short $T_{1/2}$
Astatine-211	1α	7.2 h	5.87 α	Requires cyclotron for production
Actinium-225	4α, 2β	10 days	5.75–8.7 α	Daughters a potential problem

Labeling procedures

Physical properties that are important in the selection of radionuclides for MAb conjugation include types of emitted particles (α, β, γ), emission energies, half-life, availability, cost, ease of conjugation to proteins, and capacity for imaging (Table 23.2). ^{131}I and ^{90}Y are the best studied radionuclides for RIT and both have been approved by the FDA for treatment of patients with relapsed or refractory B-cell NHL in conjunction with murine anti-CD20 MAb ([^{131}I]tositumomab and [^{90}Y]ibritumomab). ^{131}I has a half-life of 8 days and emits both β particles and γ rays. ^{90}Y is a radiometal with a short half-life (2.7 days) that emits β particles that are four times as energetic as those from ^{131}I, but virtually no γ rays, hence it cannot be easily imaged with a gamma camera. Dosimetry with ^{90}Y is therefore reliant on the administration of a surrogate γ-emitting radionuclide, such as ^{111}In.

Although the relative merits of ^{131}I and ^{90}Y have been debated extensively in the literature on theoretical grounds, no randomized controlled trial comparing them has been performed. Although ^{131}I possesses a number of favorable attributes, including a high energy γ emission energy for imaging, low cost, relative abundance, and a well-understood chemistry for protein labeling, it also possesses several limitations, including rapid release of [^{131}I]tyrosine and free ^{131}I from tumor cells after endocytosis and proteolysis of the radioiodinated MAbs, thus reducing the residence time of the radionuclide at its target [23,60]. In addition, the γ rays emitted by ^{131}I are of sufficiently high energy (364 keV) that they pose a potential safety risk to healthcare workers and require radiation isolation for patients receiving the high doses required for HCT. ^{90}Y also has limitations. It is less abundant and more expensive than ^{131}I and has been shown to accumulate non-specifically in liver and bone [61]. In addition, some groups have raised concerns about the use of ^{111}In as a surrogate for ^{90}Y dosimetry. Recently, there has been increased interest in the lanthanide radiometal ^{177}Lu, which possesses a β energy that is slightly less than that of ^{131}I, emits γ rays suitable for gamma camera imaging, and possesses a half-life of 6.7 days. The lower energy γ rays emitted by ^{177}Lu reduce the potential radiation exposure of family members and healthcare workers compared with ^{131}I. Another radionuclide, ^{67}Cu, like ^{90}Y and ^{177}Lu, is retained intracellularly following internalization. It has both γ- and β-particle emissions and a half-life suitable for RIT. In addition ^{67}Cu emits

^{99m}Tc-like photons that are suitable for imaging via positron emission tomography (PET). Expense and availability have been major limitations to the use of this radionuclide in the past; however, there has recently been renewed interest in increasing the scale of production. Rhenium isotopes ^{186}Re and ^{188}Re have also been used in some studies. Both have γ and β emissions and well-described chelation chemistries; however, the use of ^{188}Re has largely been limited by its short half-life.

α-Emitting radionuclides have considerable promise for RIT. Recent advances in the production and availability of α-emitting isotopes have sparked renewed interest in their use. These particles have a mass that is on average 7000 times that of β particles and energies that range from 3 to 13 times greater than those of the β emitters conventionally employed in RIT. This translates into significantly higher linear energy transfer (LET) for α emitters (approximately 100 keV/μm) compared with β emitters (0.2 keV/μm). LET is defined by the number of ionizations per unit distance traveled. Since the number of ionizations directly correlates with the potential to produce irreparable double-stranded DNA beaks, α particles exhibit a high relative biological effectiveness for cell killing. The α emitters possess a number of theoretical advantages compared with β emitters: they deliver higher energies over a much shorter range (path length <0.1 mm) [62], cause extensive cell damage that is independent of the dose rate, and exhibit no functional impairment in hypoxic environments, in contrast to β emitters [63]. In addition, α emitters generally pose a low risk to healthcare workers owing to their short path length. When conjugated to antibodies, the combination of high energy and short path length provides the capacity to kill only the antigen-expressing target cell while sparing surrounding normal cells, potentially reducing myelotoxicity. The absence of a significant bystander effect may not be optimal for larger volume tumors, but is favorable for targeting small tumors, micrometastasis, and individual tumor cells (i.e., minimal residual disease in patients with leukemia) [64–66]. The α-emitting radionuclides best suited for clinical application include ^{211}At ($T_{1/2}$ = 7.2 hours), ^{225}Ac ($T_{1/2}$ = 10 days), and ^{213}Bi ($T_{1/2}$ = 45.6 minutes) [63,67]. Although the short half-lives of α-emitting radionuclides complicate clinical trial design schemes, a number of groups have successfully conducted patient trials with α-emitting radionuclides conjugated to a MAb (reviewed in sections to follow).

Retaining MAb immunoreactivity is essential during the physical process of radiolabeling and great care must be taken to maintain sterility. The process can be exquisitely sensitive to external factors, including fluctuations in temperature and pH. ^{131}I can be covalently conjugated to antibodies on a tyrosine residue by either the chloramine-T or Iodogen™ methods. However, these simple approaches do not protect against rapid metabolism and release of free radioiodine when the antigen–antibody complex is internalized. Alternative processes have been developed to prevent intracellular degradation. Tyramine cellobiose involves the formation of a polysaccharide bridge between the antigen and halogen radionuclide that allows for retention of the radioligand within the cell [68]. The non-halogen radionuclides (^{90}Y, ^{111}In, ^{177}Lu) cannot be readily linked to antibodies by direct labeling and require a more complicated chemistry for attachment. This process requires the use of an intermediary molecule known as a chelate. Currently the most commonly used chelation techniques include isothiocyanotobenzyl-DTPA (diethylenetriaminepentaacetic acid) or 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*′′,*N*′′′-tetraacetic acid (DOTA).

Dosimetry

Optimal RIT treatment planning requires accurate individualized biodistribution data for calculating the predicted relative exposure of normal and target tissues from delivered radiation. In the clinical setting, this is achieved through the injection of a trace-labeled dose of antibody with subsequent serial single photon emission computed tomography or planar imaging. Activity curves for specific regions of interest are generated and compared with curves derived from banked standard tissue biopsy specimens. This approach has been validated in animal models [54]. The accuracy of this approach is compromised for small, deep-seated tumors or tissues not amenable to biopsy. Other factors limiting accuracy result from signal averaging that occurs when radionuclide content is assessed for whole organs. Current imaging techniques are incapable of identifying the heterogeneous distribution of antibody that occurs at a cellular level. This heterogeneity is most pronounced when evaluating large tumor volumes, areas with poor vascular supply, and in cases when high-affinity MAbs accumulate at the periphery of tumors and in intravascular locations due to the binding site barrier [44]. Radionuclides with longer path lengths (e.g., ^{90}Y) theoretically reduce the impact of cell–to-cell variation at the expense of irradiation of adjacent non-target tissues. In addition, the use of positron emission tomography in conjunction with photon-emitting radionuclides may improve the capacity to identify variable uptake within specific tissues [69].

Based on the measured biodistribution of the RAbs, tables have been developed by the MIRD that allow the estimation of the mean absorbed dose over a specific organ volume for any radionuclide administered [17]. This calculated dosimetry is based on formulas that weigh the contribution of the circulating radionuclide, radiation from neighboring organs to the organ of interest, and the direct contribution from the radionuclide delivered to the target site. Its accuracy can be further enhanced by radiographically quantified individualized organ volumes [70]. This system for calculating dosimetry is not optimized for α-emitting particles, because they deliver high energy over a very short range. Alternative methods involving microdosimetry have been developed for the α emitters [71].

Radiation effects

Conventional fractionated external-beam therapy is capable of delivering high doses of radiation over a short period of time. Classically fractionated doses of 1–2 Gy at 7–25 cGy/min up to a total dose of 10–15 Gy have been used in conditioning regimens for HCT. RAbs, on the other hand, deliver continuous, variable, exponentially decreasing low dose-rate radiation. Although the peak rate of radiation delivery with RIT is substantially lower than with external-beam TBI, there is continuous exposure of tumor cells to radiation, rather than intermittent exposure as with fractionated TBI. The exponential decline of radiation exposure seen with RIT is dependent on the chosen particle's half-life of decay. There has been no systematic evaluation of the biologic impact of these different delivery mechanisms. However, based on strong evidence that the cytotoxic activity of radiation is proportional to its capacity to induce DNA strand breaks, some have suggested a potential advantage arising from continuous radiation exposure that prevents intervals during which cellular DNA repair can occur [72]. Consistent with this hypothesis, a number of human solid tumor xenograft experiments have demonstrated RAbs to have equivalent or even enhanced antitumor activity compared with external-beam radiation [73,74]. Another potential explanation for this finding relates to what has been described as an "inverse dose-rate effect".

At some dose-rate ranges, a lower dose is assumed to be more cytotoxic than a larger dose. It is theorized that this seemingly paradoxical finding is related to induction of cell cycle arrest in cells exposed to a continuous low dose-rate of radiation in the G2 phase of the cell cycle. Since the G2/M interface is the most radiosensitive phase of the cell cycle, the presence of a larger proportion of cells in this phase is believed to increase cytotoxicity. Likewise, there is preclinical evidence to suggest that low dose-rate radiation may best synergize with chemotherapeutics that are involved with interference with single-stranded DNA repair such as the nucleoside analogs [75].

Leukemia

The first studies integrating RIT into HCT targeted the CD33 myeloid-associated glycoprotein in patients with AML. These studies employed [^{131}I]anti-CD33 (p67) followed by a standard CY/TBI (12 Gy) preparative regimen. This regimen was selected because it provided adequate immunosuppression to ensure engraftment, while allowing the possibility for dose escalation of the RAbs. CD33 was selected for initial targeting studies since this antigen is expressed on the leukemic cells in over 90% of AML cases (and also on normal myeloblasts, myelocytes, and metamyelocytes, but not on any non-hematopoietic cells).

As noted previously, identifying a favorable biodistribution of radioactivity as defined by a trace-labeled test dose of MAbs that distributed radiation preferentially to bone marrow and spleen was considered essential prior to delivering a therapeutic RAb dose in these initial studies. The first small trial in Seattle enrolled nine patients, and only four met the biodistribution criterion required by the protocol for proceeding to the therapeutic [^{131}I]anti-CD33 infusion (estimated radiation doses to marrow and spleen that were greater than to any normal organ) [76]. Although all four patients tolerated both the therapeutic infusion of [^{131}I]anti-CD33 MAbs and subsequent HCT without unexpected toxicities, three subsequently relapsed. Eradication of AML cells in this study was likely compromised by the relatively brief residence time of [^{131}I]anti-CD33 MAbs in target tissues (9–41 hours). The rapid clearance of radioactivity from the marrow and spleen was thought to result from rapid internalization of the antibody–antigen complex followed by cellular metabolism of the radioimmunoconjugate resulting in the release of ^{131}I and [^{131}I]tyrosine from the marrow space. In addition, the relatively low density of CD33 per cell resulted in antigenic saturation at doses greater than 0.5 mg/kg. These considerations prevented dose escalation and the study was halted. Despite these limitations, this initial study documented the feasibility of integrating RIT into HCT preparative regimens.

In parallel with the studies in Seattle, investigators at the Memorial Sloan Kettering Cancer Center (MSKCC) in New York also conducted trials targeting CD33 for myeloid leukemias. These studies employed a ^{131}I-labeled murine MAb called M195. Whereas initial biodistribution studies revealed findings similar to the Seattle p67 experience with low concentrations of MAb administered prior to saturation, the reported half-life of ^{131}I in the marrow was somewhat longer. Their first trial of 24 patients with myeloid malignancy involved a dose escalation design. The labeled M195 was administered in divided doses, to allow for CD33 re-expression. About 90% of enrolled patients demonstrated a dramatic decrease in peripheral and marrow blasts. With ^{131}I doses of 5 GBq (135 mCi/m^2) or greater, profound pancytopenia ensued and, while HCT was not required by the study design, eight patients who received <5.9 GBq (160 mCi/m^2) received autologous or allogeneic HCT rescue. In a subsequent study integrating radiolabeled M195 into a busulfan (BU)–CY allogeneic HCT preparative regimen for patients with relapsed or refractory AML, the MSKCC group reported 100% engraftment, with 18 of 19 study subjects achieving a remission.

As a refinement, the MSKCC group developed a humanized version of M195 (HuM195) with pharmacokinetic properties similar to murine M195, but without significant immunogenicity [77]. Cumulative long-term follow-up data from three phase I clinical trials investigating [^{131}I]anti-CD33 antibodies in combination with BU–CY as a conditioning regimen for relapsed or refractory AML ($n = 16$), accelerated/myeloblastic CML ($n = 14$), or advanced myelodysplastic syndrome (MDS) ($n = 1$) revealed a median survival for all patients of 4.9 months (range, 0.3–90+ months) after HCT. The intensified conditioning with [^{131}I]anti-CD33 antibodies resulted in few toxicities beyond those seen with standard BU–CY preparative regimens. A number of limitations were associated with the M195 and HuM195 constructs, however. Radioiodination of these anti-CD33 MAbs at high specific activity decreased the CD33 binding affinity and, as a result, patients required multiple MAb infusions to deliver myeloablative doses to the marrow. In addition, the high doses of ^{131}I required patient isolation to prevent high-energy (γ) emission exposure to hospital staff [58]. To avoid some of these limitations, the MSKCC group subsequently investigated the role of ^{90}Y as the therapeutic radionuclide and demonstrated the feasibility of this approach [78].

In the non-HCT setting, HuM195 conjugated to the α emitter ^{213}Bi has been investigated [79]. A feasibility trial involving 18 patients with either relapsed/refractory AML or chronic myelomonocytic leukemia demonstrated the safety and feasibility of α-particle therapy [80]. All patients developed myelosuppression and the absorbed dose ratios between sites of leukemic involvement (spleen, marrow, and liver) and whole body were reported to be 1000-fold greater than would be seen with β-emitting constructs. However, although 93% of patients experienced a decrease in peripheral blast counts and 78% experienced reductions in marrow blast counts, no complete remissions (CRs) were achieved. There were several limitations associated with this study. First, no maximum tolerated dose was identified because escalation beyond 37 MBq/kg was restricted by production capacity and cost. Second, the patient population studied carried a heavy tumor burden (average 10^{12} cells) that may not be well suited to the short range and high LET properties of α particles. Nevertheless, incorporation of this approach into HCT conditioning regimens for patients in CR or near CR remains a promising prospect, especially with alternative α emitters such as ^{225}Ac [65,81].

Owing to the limitations associated with CD33 targeting identified in their early studies, investigators at the Fred Hutchinson Cancer Research Center (FHCRC) in Seattle selected an alternative target, the protein tyrosine phosphatase CD45, for subsequent investigations. Termed the common leukocyte antigen, CD45 is expressed on the surface of virtually all cells of hematopoietic origin except mature erythrocytes and platelets. CD45 possesses a number of potentially advantageous characteristics for RIT targeting. While the overall percentage of AML and ALL patients whose leukemic cells express CD45 is virtually equivalent to CD33 (85–95% versus 90%), the receptor density is 10-fold greater (100,000–200,000 versus 10,000–20,000 antigenic sites per leukemic cell). In contrast to CD33, which is rapidly internalized after antibody–receptor complex formation, the CD45 antigen remains stably fixed on the cell surface. After a series of murine and non-human primate studies revealing favorable biodistributions with the BC8 anti-CD45

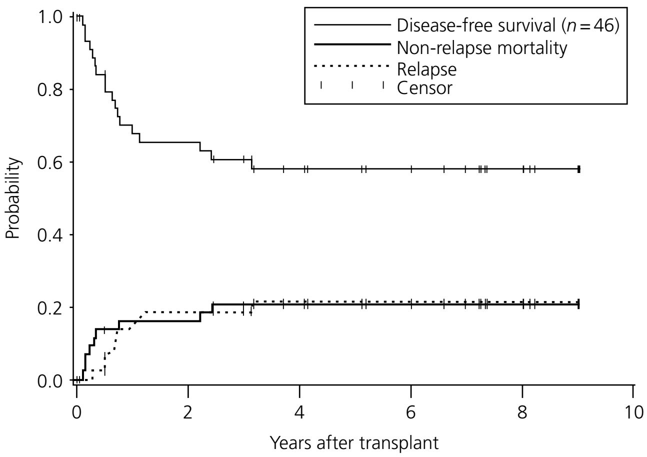

Figure 23.1 Estimates of the probability of disease-free survival, non-relapse mortality, and cumulative risk of relapse among 46 patients with AML in first complete remission who received a therapeutic dose of [^{131}I] BC8 (102–298 mCi) followed by busulfan–cyclophosphamide and allogeneic HCT. Figure 23.2 Estimates of the probability of overall survival, disease-free survival, non-relapse mortality, and cumulative risk of relapse among patients treated at the MTD of 24 Gy of radiation delivered to the liver by [^{131}I]BC8 MAbs followed by TBI–fludarabine. Source: Pagel J.M. et al. 2009. Allogeneic hematopoietic cell transplantation after conditioning with ^{131}I-anti-CD45 antibody plus fludarabine and low-dose total body irradiation for elderly patients with advanced acute myeloid leukemia or high-risk myelodysplastic syndrome. *Blood* 2009; **114**: 5444–5453. Reproduced with permission of the American Society of Hematology.

MAb, a phase I trial for patients with AML or ALL was initiated, employing an design identical with that of the FHCRC p67 trial [56,82]. The theoretical advantages of CD45 targeting were validated in this trial that exhibited an improved biodistribution profile compared with the prior CD33 targeting experience. The improved biodistribution was likely a function of improved hematopoietic tissue targeting due to a larger number of antigenic sites and a period of red marrow retention that was more than double that seen in the p67 study ($T_{½}$ = 44.2 versus 21.4 hours). Of the 44 patients initially enrolled, 37 had favorable biodistributions (84%) with an average 2–3-fold greater radiation delivered to the marrow than to the liver, which was the normal organ with the highest radiation exposure.

These findings led to a subsequent study for patients with AML in CR1 employing [^{131}I]BC8 MAb combined with a standard preparative regimen of targeted BU 600–900 ng/mL and CY 120 mg/kg. The MAb biodistribution was favorable in 88% of patients. Forty-six patients were treated with 102–298 mCi (3744–11026 MBq) of [^{131}I] BC8 MAb combined with BU–CY, with all but three receiving estimated radiation doses of 5.25 Gy to the liver and average estimated radiation absorbed doses of 11.3 Gy to the bone marrow and 29.7 Gy to the spleen. Overall, 61% of patients were surviving disease free at a median of 3 years after HCT, with eight transplant-related deaths and eight relapses (Figure 23.1). Based on an intention-to-treat analysis, the study patients were compared with an International Bone Marrow Transplant Registry cohort of 509 patients treated with BU–CY alone. Following adjustment for age and cytogenetic risk, the hazard of mortality among the [^{131}I]BC8 RIT treated patients was 0.65 (95% CI, 0.39–1.08; p = 0.09). Subgroup analysis revealed the overall 3-year survival to be 75% (95% CI, 58–92%) among patients with intermediate-risk cytogenetics and 36% (95% CI, 11–62%) for those with unfavorable cytogenetics [83].

These results suggested that this approach might well be applied to older patients. A phase 1 dose escalation trial using [^{131}I]BC8 combined a reduced-intensity conditioning (RIC) approach followed by HCT was conducted for a particularly poor-risk population of patients with advanced AML and high-risk MDS who were older than 50 years of age [84]. This study demonstrated that [^{131}I] BC8 could deliver 5.2–45.9 Gy (mean, 27.5 Gy) to bone marrow, 17.3–155 Gy (mean, 81.2 Gy) to spleen, and 12–24 Gy to the liver (dose-limiting organ) in addition to a standard RIC HCT regimen without a marked increase in day 100 mortality (Figure 23.2) [84]. A remission was achieved in all patients and all had 100% donor CD3$^+$ and CD33$^+$ cell engraftment by day 28 post-transplant. Whether the use of a RAb combined with an RIC transplant will reduce post-transplant relapse for these older patients with high-risk AML/MDS remains to be determined, however.

So far, the majority of clinical experience in targeting CD45 with radioimmunoconjugates has been accumulated with ^{131}I. However, limited data obtained with YAML568, a rat IgG2a MAb that recognizes all CD45 isoforms, suggest that other anti-CD45 MAbs can selectively deliver radiation to hematopoietic tissues when labeled with ^{90}Y, provided that patients are preloaded with unlabeled antibody [57]. In Germany, a number of groups have explored CD66 (a, b, c, e) as an alternative target for patients with MDS or AML. CD66 is expressed at high levels on the surface of normal myeloid cells beyond the promyelocyte stage, but not on leukemic blasts. It is neither internalized nor shed. Targeting this receptor requires that the delivered radionuclide kill tumor cells entirely via by-stander radiation delivered from adjacent non-leukemic cells in the marrow space. Fifty-five patients with AML or MDS who were in CR or partial remission (PR) but judged to be at high risk for relapse after standard HCT were enrolled in this phase I/II trial [40]. All patients enrolled had favorable initial biodistributions and received a therapeutic dose of [^{188}Re]anti-CD66 MAb delivering a mean of 15.6 Gy of additional radiation to the marrow. Patients were then treated with a variety of full-dose conditioning regimens followed by allogeneic HCT. T-cell depletion for graft-versus-host disease (GVHD) prophylaxis was achieved by either CD34$^+$ selection or administering Campath-1H in the donor cell infusion bag. The kidney was the organ receiving the highest dose of supplemental radiation (mean, 7.2 Gy) and late renal toxicity was a complication in 11% of patients with an incidence correlating with the renal dose exposure. There was no increase in treatment-related mortality associated with the addition of RIT. Patients transplanted in CR or good PR (<15% blasts in the marrow) had the best outcomes, with 59% disease-free at median follow-up. In contrast, only 8% of patients who had more than 15% blasts in the marrow were alive at this time point [85]. Less promising results were reported in another study in which [^{188}Re]anti-CD66 was combined with a conventional preparative regimen. A significantly higher rate of transplant-related toxicity and acute GVHD was reported with a transplant-related mortality of almost 50% (nine of the 19 patients enrolled), likely due, at least in part, to the advanced AML or ALL patients treated on this study [86].

Non-Hodgkin lymphoma

NHL cells are ideal targets for RIT because of their exquisite radiosensitivity and their stable expression of well-characterized lineage-specific surface antigens. The direct cytotoxic effect of targeted radiation obviates the need for reliance on the host's immune effector mechanisms, which are frequently impaired in NHL patients. The approval of two CD20 targeted radioimmunotherapeutic agents by the FDA for the treatment of relapsed or refractory follicular and transformed follicular NHL {[^{131}I]tositumomab (Bexxar™) and [^{90}Y]ibritumomab-tiuxetan (Zevalin™)} generated excitement about the promising results seen with both standard and high-dose myelosuppressive treatment regimens.

Some of the earliest NHL patient studies using MAbs employed patient-specific anti-idiotypic antibodies raised against the tumor-specific clonal idiotype of the immunoglobulin (Ig) molecule expressed on B-cell malignancies [87,88]. These trials produced promising results with durable (>5 years) objective remissions in 60–70% of patients studied; however, the technical and financial limitations inherent in patient specific production of anti-idiotypic antibodies rendered the widespread use of this approach infeasible. Subsequently, most investigators focused on targeting lymphocyte differentiation antigens expressed on both normal and malignant lymphoid cell surfaces. The CD20 antigen was a particularly attractive target because of its high density (~150,000/cell) and the presence on more than 90% of B-cell tumors [89]. Further, most investigators believe that it is minimally shed or internalized following antigen binding and, while present on almost all B-lymphocytes, the temporary elimination of normal B cells by anti-CD20 antibodies has not proven a significant limitation.

Initial studies with unmodified murine anti-CD20 MAb were of limited success owing to the restricted capacity of murine Ig to fix human complement or mediate antibody-dependent cell-mediated cytotoxicity (ADCC) with human effector cells. The first patient studies, conducted by Press et al. in Seattle, demonstrated that high doses of the murine anti-CD20 MAb 1F5 could be administered safely to patients, and in individuals receiving the highest doses, dramatic albeit short-lived remissions could be achieved [90]. These initial studies helped to pave the way for the development of a human–mouse chimeric anti-CD20 MAb, rituximab, which ameliorated the murine MAb-associated limitations [91]. Early studies by Maloney et al. reported objective remissions in 46% of patients treated with rituximab in a multicenter phase II trial [92]. These results were confirmed in a subsequent study in which 48% of patients with indolent NHL achieved objective responses and 6% achieved CR. The median duration of response was approximately 1 year [93].

Although the initial studies with rituximab were encouraging, almost half of all patients with relapsed indolent NHL and 60–70% of patients with relapsed aggressive lymphomas failed to respond to single-agent rituximab. Furthermore, only 5–10% of patients with indolent NHL achieved CR with rituximab and the median response duration was less than 1 year. In light of these factors, a number of investigators continued to pursue mechanisms for amplifying the therapeutic promise of MAbs by conjugating them to radionuclides.

The first studies to evaluate the potential efficacy of RAbs in NHL were conducted by DeNardo et al. in the mid-1980s [94]. In these studies, an antibody recognizing a DR variant antigen (Lym-1) was conjugated to ^{131}I. DeNardo's group demonstrated both the feasibility and safety of RIT in a population of advanced-stage patients with relapsed B-cell malignancy; moreover, they documented an objective remission rate of approximately 50% in a population of patients with disease that had been resistant to standard therapy. Subsequently, a robust literature developed reporting clinical trial data that demonstrated the safety and efficacy of non-myeloablative RIT in B-cell NHL. While most centers focused on CD20-targeted RIT at standard non-myeloablative doses without the need for hematopoietic progenitor support, two basic approaches have emerged for incorporating RIT as part of a transplant conditioning regimen for NHL. The first approach maximizes the therapeutic potential of RIT by escalating the dose to the non-hematopoietic toxicity threshold either with or without high-dose chemotherapy much akin to the use of high-dose TBI. A second tactic adds standard non-myeloablative doses of RIT to a maximized myeloablative chemotherapy conditioning regimen.

Myeloablative RIT-based autologous conditioning regimens

In the mid-1980s at the FHCRC in Seattle, a series of studies were initiated to investigate the possibility of replacing external-beam TBI with targeted RIT as a conditioning regimen for HCT [95]. Integration of RIT into HCT conditioning regimens was tested to determine if it could maximize the tumor-to-normal organ ratios of delivered radiation, thereby improving cure rates while minimizing additional toxic effects. The first such study was designed to compare the biodistribution profiles for a number of different B-cell antibodies, to determine the impact of MAb dose on biodistribution, and to assess the toxicity and potential efficacy of increasing doses of ^{131}I conjugated to the B-cell antibodies under study [21,96]. This phase I dose-escalation trial studied the biodistribution of anti-CD37 and anti-CD20 MAbs in 43 patients with relapsed B-cell NHL. In the patients who received therapeutic infusions, maximal doses to normal organs were calculated according to dose-escalation parameters allowing delivery of radiation between 10 and 31 Gy to critical normal organs with therapeutic ^{131}I doses ranging from 234 to 777 mCi. Pulmonary doses of 27 Gy defined the maximum tolerated dose (MTD) with two of four patients developing reversible cardiopulmonary toxicity at this level. Objective responses were seen in 95% of patients receiving therapeutic infusions of ^{131}I-MAb with 85% achieving a CR. Eight patients remained in CR 46–95 months following therapy.

Patients assessed with anti-CD20 MAbs (tositumomab or 1F5) exhibited biodistributions demonstrating superior targeting compared with the other MAbs evaluated (anti-CD37 and anti-idiotype). Based on this finding, a phase II study with high-dose [^{131}I-]tositumomab (formerly known as anti-B1 MAb) was performed. The regimen was well tolerated with minimal toxicity compared with standard TBI based conditioning regimens. Furthermore, in a series of 125 consecutive patients with indolent B-cell NHL undergoing high-dose conditioning and autologous HCT, the outcomes in the RIT patients compared favorably in a multivariate model with the control population treated with conventional autologous HCT conditioning regimens [48% 5-year progression-free survival (PFS) in the RIT group versus 29% in the conventional transplant group, $p = 0.03$] [97].

Although the rates of CR and prolonged remissions in this population with multiply relapsed B-cell NHL were encouraging, maximal doses of RIT with stem-cell support still averted eventual relapse in only about 50% of the patients studied. To improve further the fraction achieving durable CR, Press et al. conducted a phase I/II study combining [^{131}I]tositumomab with high-dose etoposide, CY, and autologous HCT [72]. Fifty-two patients under the age of 60 years were treated on this protocol and the MTD was determined as 25 Gy of ^{131}I-tositumomab (1.7 mg/kg), 60 mg/kg etoposide and 100 mg/kg CY. At 2 years, the estimated overall survival for all 52 patients enrolled was 83% and PFS was 68%. When compared with a non-randomized control group of 105 NHL patients who were treated with TBI–CY–etoposide and autologous HCT in a multivariate analysis that incorporated disease grade (indolent versus aggressive), stage, and chemosensitivity, the patients in the RIT-based conditioning regimen group demonstrated superior PFS and overall survival (OS) [Figure 23.3; 38% ($p = 0.006$) and 50% ($p = 0.01$)].

Patients with mantle cell lymphoma (MCL) comprise 4–10% of all NHL and represent a special challenge as they exhibit the poorest long-term survival of any lymphoma subtype. There is no consensus regarding optimal first-line treatment for MCL patients and the disease is generally considered incurable with chemotherapy regardless of the regimen employed (survival ~2–3 years) [98]. Furthermore, conventional HCT performed after relapse has generally been unsuccessful [99,100]. The Seattle group performed a pilot study evaluating outcomes in 16 patients with relapsed MCL with the above autologous HCT conditioning regimen employing [^{131}I]tositumomab followed by CY and etoposide [101]. As a result, the overall response rate for the small number of evaluable patients was 100% with 91% achieving a CR. A large ($n > 100$) phase II trial by the Seattle group evaluating this combined high-dose chemo-RIT approach in patients with aggressive, indolent, and MCL has completed accrual and is expected to be reported soon.

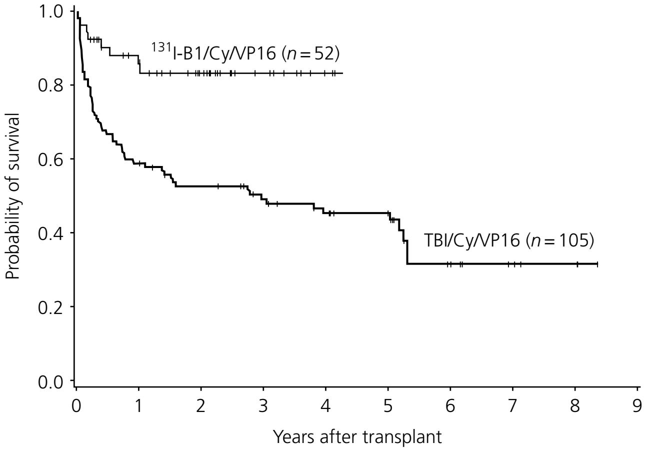

Figure 23.3 Overall survival of patients with relapsed B-cell lymphomas who underwent high-dose chemoradiotherapy including either [^{131}I] tositumomab at myeloablative doses (52 patients; top line) or a standard total body irradiation (TBI)-based preparative regimen (105 control patients; bottom line) followed by autologous HCT. Patients in the RIT group received up to 25 Gy to normal organs; the TBI group received 1.5 Gy twice per day for 4 days. Both groups were treated with identical doses of etoposide and cyclophosphamide. Source: Press et al. 2000 [72]. Reproduced with permission of the American Society of Hematology.

A similar strategy was also employed by Nademanee et al. at the City of Hope Cancer Center, where [^{90}Y]ibritumomab tiuxetan was escalated in place of TBI and combined with 60 mg/kg etoposide and 100 mg/kg CY prior to autologous HCT [102]. In this phase I/II trial, patients were given escalating doses of radiation based on dosimetry during phase I, and the MTD to critical organs was calculated to be 10 Gy. Subsequently, 31 patients with follicular ($n = 12$), diffuse large B-cell ($n = 14$), and MCL ($n = 5$), including seven in first CR or PR, were treated with 10 Gy of [^{90}Y]ibritumomab tiuxetan (36.6–105 mCi) in combination with either 40 mg/kg (cohort 1; six patients) or 60 mg/kg (cohort 2; 25 patients) of etoposide and a fixed-dose CY (100 mg/kg). There were five relapses and 24 of the 31 patients were alive and in remission at a median follow-up of 22 months after therapy. The 2-year RFS and OS were 78% and 92%, respectively. These findings provide further data on the promise of integrating CD20-targeted RIT into HCT conditioning regimens. Although it is enticing to compare the results from this ^{90}Y-based trial with ^{131}I findings reported by Press et al., it should be reiterated that the patient profiles in these two studies were very different in terms of inclusion criteria, differences in radiation dose, and number of prior therapies. A similar study of relapsed and refractory B-cell NHL patients was conducted by Winter et al. at Northwestern University [26]. In this phase I trial, 44 patients received dose-escalated [^{90}Y]ibritumomab followed by high-dose carmustine, etoposide, cytarabine, and melphalan (BEAM) and autologous HCT. One patient developed transient veno-occlusive disease at the 700 cGy level and two dose-limiting toxicities occurred at the 1700 cGy dose level; one patient developed grade IV stomatitis on day 10 and a second patient developed septic pulmonary emboli on day 13. In addition, one heavily pretreated patient developed MDS on day 291. With a 21-month median follow-up, the 3-year OS and PFS were 52% and 37%, respectively.

Patients aged over 60 years comprise over half of all new diagnoses of NHL in the United States and are at particularly high risk for poor outcomes when diagnosed with NHL [103], yet individuals in this age group have been excluded from most HCT trials owing to concerns about the toxicity of the conditioning regimens. Gopal et al. sought to exploit the reduced non-specific normal organ toxicity seen with RIT-based conditioning regimens in a phase II safety and efficacy trial employing single-agent high-dose [^{131}I]tositumomab conditioning prior to autologous HCT for this group of older adults [104]. Twenty-four heavily pretreated NHL patients ≥60 years of age (median age 64 years) received 328–1154 mCi of [^{131}I]anti-CD20 RAb to deliver a maximum of 25–27 Gy to critical organs. The estimated 3-year OS and PFS rates were 59% and 51%, respectively. Based on these promising safety and efficacy data, the desire to improve outcomes further, and the preclinical data suggesting a potent supra-additive effect for RIT combined with nucleoside analogs [75,105], a phase I trial of combined fludarabine–[^{131}I]tositumomab trial for patients ≥60 years has been completed [106]. This study of 36 B-cell NHL patients with a median age of 65 years (range, 60–76 years) demonstrated that up to 210 mg/m^2 of fludarabine could be delivered concurrently with [^{131}I] tositumomab delivering ≤27 Gy to critical normal organs. Toxicity was again moderate compared with conventional high-dose regimens with no early treatment-related deaths, 69% of patients remained outpatients following discharge from radiation isolation, and only two developed grade 4 non-hematologic toxicity (hypokalemia and depression) with a 3-year PFS of 52%.

More recently, high-dose RIT approaches have also been explored by other groups. Ferrucci et al. dose escalated [^{90}Y]ibritumomab tiuxetan based on weight, using three predefined dose levels (0.8, 1.2, and 1.5 mCi/kg) [107]. Patient-specific dosimetry was performed in all cases to evaluate the distribution of activity in critical organs. Absorbed doses to target organs were highly variable for any of the cohorts. At the most recent update, 25 patients were reported including those at the highest dose level of 1.5 mCi/kg [108]. The median activity of ^{90}Y was 100 mCi and all patients engrafted promptly. Similarly, Devizzi et al. in Milan reported on 29 patients with B-cell NHL who received either 0.8 or 1.2 mCi/kg followed by tandem reinfusions of mobilized peripheral blood progenitor cells on days +7 and +14 [109]. No significant non-hematologic toxicities were reported and engraftment was rapid, although it cannot be concluded that the tandem infusions were of benefit over the conventional approach. Flinn et al. likewise dose escalated [^{90}Y] ibritumomab tiuxetan with mobilized peripheral blood progenitor cell support in patients with relapsed or refractory B-cell NHL [110]. As suggested by these three series, dose escalation of single-agent ^{90}Y-ibritumomab tiuxetan is possible, but whether dose escalation should be performed using dosimetry to define a specific absorbed dose to the critical organ or by weight remains to be established. If dosed according to weight, 1.2–1.5 mCi/kg would appear to be the preferred dose range.

Other groups have also investigated high doses of single-agent RIT, including a small trial conducted in Germany. Behr et al. reported on seven patients treated with potentially myeloablative doses of either [^{131}I]rituximab (five patients) or a humanized]^{131}I] anti-CD22 MAbs (two patients). Complete responses were reported in all five patients who received stem-cell support [111].

Other RIT targets have also been explored in a more limited fashion in this setting. The CD22 surface receptor has been targeted by a number of groups. Goldenberg's group reported on three patients treated with potentially myeloablative doses (90 mCi/m^2) of [^{131}I]anti-CD22 (LL2 IgG) followed by autologous bone marrow support. The two evaluable patients had PR lasting 2 and 8 months [112]. Vose et al. treated 21 patients in a phase I/II trial using multiple doses of [^{131}I]LL2 MAb with an overall CR rate of 24% [113]. Five patients in this study required autologous HCT due to prolonged cytopenias. Based on preclinical data, the Seattle group is currently evaluating targeting the pan-hematopoietic antigen CD45 as a method to treat both T- and B-cell NHL and circumvent the potential risk of CD20 blocking by rituximab [27,114].

One of the limitations associated with high-dose ^{131}I RIT conditioning regimens is the requirement that patients remain in inpatient isolation until their body radiation levels return to safe levels. Likewise, the use in RIT of doses of ^{90}Y above what is commercially available can pose technical and financial challenges. To study the efficacy of a straightforward outpatient-based approach, a phase I trial was conducted combining conventional, non-myeloablative doses of [^{131}I]tositumomab with the BEAM high-dose chemotherapy regimen followed by autologous HCT in 23 patients with aggressive chemo-refractory NHL. The total body dose of radioimmunoconjugate was escalated up to the standard 75 cGy dose approved for this radiopharmaceutical. There was no significant difference in toxicity for patients receiving 75 cGy of ^{131}I compared with patients receiving high-dose BEAM alone. The CR rate after HCT was 57% and the overall response rate was 65%. At a median follow-up of 38 months, event-free survival and OS were 39% and 55%, respectively [115,116].

A subsequent phase II trial by the City of Hope Cancer center employed a similar strategy with encouraging results by adding [^{90}Y]ibritumomab tiuxetan to high-dose BEAM chemotherapy conditioning prior to autologous HCT. Forty-one patients with B-cell NHL whose age or prior radiotherapy deemed them ineligible for TBI or high-dose [^{90}Y]ibritumomab tiuxetan were studied. All patients received a standard non-myeloablative dose of [^{90}Y]ibritumomab (0.4 mCi/kg), with no dose adjustment for neutropenia or thrombocytopenia, followed by high-dose BEAM therapy 1 week later. After a median follow-up of 18.4 months, the estimated 2-year OS was 88.9% and PFS was 69.8% [117]. Overall, the rates of treatment-related toxicities were not different from those reported for patients receiving BEAM therapy alone. A subsequent multivariate comparison of the study patients with those treated with TBI-based conditioning favored the RIT plus BEAM approach [118].

Shimoni et al. in Israel have also reported on the use of combined standard-dose [^{90}Y]ibritumomab tiuxetan with high-dose BEAM chemotherapy for aggressive NHL [119]. Their findings were similar to those in the previous studies with an overall CR rate of 76% in the 21 evaluable patients (of the 16 patients in CR, five were initially in PR but reached CR after additional radiation). The 2-year PFS and OS were 52% and 67%, respectively. These data led to at least two randomized phase III trials evaluating the potential benefit of adding standard-dose anti-CD20 RIT to BEAM versus BEAM or rituximab–BEAM. The largest study to date, led by Vose et al., compared [^{131}I]tositumomab plus BEAM with rituximab plus BEAM in patients with relapsed or refractory diffuse large B-cell lymphoma (DLBCL) [120]. Disappointingly, OS, PFS, and relapse rates were similar in both groups, with the best predictor of outcome in either arm being pre-transplant CR. A second randomized trial was reported by Shimoni et al. This study compared standard [^{90}Y]ibritumomab tiuxetan (0.4 mCi/kg, 32 mCi maximum) plus BEAM with BEAM alone, again with autologous stem-cell support [121]. In contrast to the study by Vose et al., patients receiving [^{90}Y]ibritumomab tiuxetan plus BEAM demonstrated an improved 2-year OS compared with those receiving BEAM alone (91% versus 62%; p = 0.05). A multicenter expansion of this trial is under way to confirm or refute these results.

RIT-based allogeneic transplant conditioning regimens for NHL

Until recently, limited data were available on the use of RIT in conditioning regimens for allogeneic HCT, primarily in the form of case reports and small case series [122]. Within the last few years, there have been at least four series evaluating the use of RIT as part of an allogeneic transplant conditioning regimen for NHL. Shimoni et al. described a series of 12 B-cell NHL patients who received standard [^{90}Y]ibritumomab tiuxetan (0.4 mCi/kg, capped at 32 mCi) on day −14 prior to a regimen on fludarabine either BU (n = 6) or melphalan (n = 6) [123]. The 2-year PFS and non-relapse mortality (NRM) were 33% and 42%, with the best outcomes observed in the three patients with follicular NHL. These data suggested that this approach was feasible, but this regimen yielded a high NRM rate due to acute GVHD in most patients, attributed to an abbreviated duration of GVHD prophylaxis. Bethge et al. conducted a prospective multicenter trial of standard [^{90}Y]ibritumomab tiuxetan (0.4 mCi/kg, capped at 32 mCi) prior to a conditioning regimen of fludarabine and 2 Gy TBI followed by allogeneic HCT from matched donors [124]. This study included 40 patients with relapsed/refractory indolent B-cell NHL or MCL without pre-transplant progressive disease. The 2-year OS and EFS of these patients were 51% and 43%, respectively, with a 45% 2-year cumulative incidence of NRM. The best outcomes were observed in those with follicular NHL, chronic GVHD, and acute GVHD less than grade 3.

Gopal and colleagues published a similar trial of 40 patients with relapsed/refractory B-NHL using standard [^{90}Y]ibritumomab tiuxetan (0.4 mCi/kg, capped at 32 mCi) prior to a fludarabine and 2 Gy TBI conditioning regimen with matched related or unrelated allogeneic HCT [125]. Notable differences between this trial and that of Bethge et al. were the inclusion of patients with aggressive B-cell NHL, the exclusion of patients who were in CR prior to HCT, and earlier administration of fludarabine in the conditioning regimens to maximize the potential antitumor synergy between RIT and the nucleoside analog. The estimated 30-month survival, PFS, and NRM of this approach were 54.1%, 31.1%, and 15.9%, respectively. Again, the best outcomes were seen in those patients with indolent histology and those with baseline platelet counts over 25,000/μL and related donors. Notably, disease control and outcomes were excellent in those who achieved a CR or PR by 3 months post-HCT, suggesting that if early disease control can be achieved, long-term remissions can be maintained by the allogeneic graft. Khouri et al. also published data evaluating standard [^{90}Y]ibritumomab tiuxetan (0.4 mCi/kg, capped at 32 mCi) prior to a fludarabine–CY-based conditioning and allogeneic transplant in 26 patients with relapsed follicular NHL [126]. Patients in this trial also experienced an excellent outcome, with 80% alive and progression free at 3 years.

A second study by Bethge's group evaluated the ability to improve outcomes further in patients with aggressive B-cell NHL by further escalating the dose of ^{90}Y [127]. This phase I trial of 20 patients demonstrated that ^{90}Y up to 0.8 mCi/kg could be safely administered prior to a fludarabine, melphalan, and alemtuzumab conditioning regimen, although the long-term survival in this extremely high-risk group of patients was only 20%. Building on this approach and the data using high-dose [^{90}Y]ibritumomab tiuxetan prior to autologous transplantation, the Seattle group is currently conducting a phase II trial of 1.5 mCi/kg prior to fludarabine, 2 Gy TBI, and allogeneic HCT for patients with aggressive B-cell NHL. Overall, data collected to date indicate that standard or moderately escalated [^{90}Y]ibritumomab tiuxetan can be safely added to a variety of allogeneic RIC regimens and may yield improved outcomes in patients with refractory or bulky indolent B-cell NHL with little additional toxicity, although comparative trials would be required to verify this hypothesis.

Hodgkin lymphoma

The protein antigen ferritin is found at elevated concentrations in the Reed–Sternberg cells of Hodgkin lymphoma. Polyclonal antiferritin antibodies labeled with ^{131}I were initially studied at nonmyeloablative [128,129] and myeloablative [130] doses, documenting the safety and efficacy of this approach. Schnell et al. reported a trial with [^{131}I]anti-CD30 MAbs in patients with Hodgkin disease [131]. Although the patient population in this study admittedly had highly resistant disease with a majority having failed prior autologous HCT, the selection of CD30 as a target antigen may also have been a limitation to the success of this approach. The presence of CD30 is limited to Reed–Sternberg cells that have a relatively sparse distribution, hence only a small amount of radioactivity can be delivered to target sites using anti-CD30 MAbs. More recently, Dancey et al. reported the use of ^{131}I-labeled anti-CD25 MAbs in patients with Hodgkin lymphoma [132]. Given the limited antigenic targets on the Reed–Sternberg cells, an alternative strategy is to target bystander cells, for example via the CD45 antigen that is present on most all hematolymphoid cells, and rely on a principle of cross-fire to deliver the therapeutic radionuclide.

Solid tumors

Solid tumors are generally less sensitive to the effects of radiation than hematologic malignancies and therefore less attractive for studies of RIT. Nevertheless, selected tumor types are sufficiently radiosensitive to merit evaluation with this approach. DeNardo et al. at the University of California (Davis) have explored ^{131}I-labeled chimeric MAbs reactive with the L6 cell-surface antigen, highly expressed on lung, breast, colon, and ovarian carcinomas [133]. In a small study, three patients were given ^{131}I-labeled MAbs followed by autologous stem-cell rescue, with one patient demonstrating a minimal response.

Anti-carcinoembryonic antigen (CEA) MAbs have been generated against a variety of CEA epitopes and used for therapy in a variety of tumors of epithelial origin. In breast cancer patients, a murine IgG1 MAb, T84.66, was studied in six patients treated with [^{90}Y]DTPA-cT84.66 followed by autologous HCT [134]. Patients received between 15 and 22.5 mCi/m^2. All showed temporary but measurable therapeutic responses and the MTD was not reached. Another group reported phase I dose-escalation data using high-dose ^{90}Y conjugated to a MAb reactive with a human milk fat-associated antigen (BrE-3) [135]. In this study, nine patients with advanced breast cancer were treated with 15–20 mCi/m^2 of [^{90}Y]BrE-3. Four of eight patients had partial responses. Anti-MUC-1 MAb 170H.82 is directed against an asialo-GM1 antigen that is highly expressed in adenocarcinoma of the breast. This anti-MUC-1 MAb was labeled with ^{90}Y and given to three patients with metastatic breast cancer with subsequent reinfusion of previously collected peripheral blood stem cells (PBSCs). A PR was reported in one patient [136]. A second study by the same group reported on three additional patients who received PBSC infusion to hasten hematopoietic recovery after ^{90}Y-labeled anti-MUC-1 MAb therapy. Two patients experienced a minor reduction in soft tissue disease lasting less than 1 month [137]. Autologous stem-cell support has also been used to enable dose escalation with [^{131}I]anti-CEA MAbs in patients with metastatic medullary thyroid cancer [138] and in children with neuroblastoma receiving ^{131}I-labeled 3F8 anti-GD2 MAbs [139]. Most studies of RIT for solid tumors since those described above have focused on its use without stem-cell support.

Toxicity

Toxicity, in the context of RAbs in HCT, falls into three general categories: acute infusional reactions, short-term toxicities associated with radiation delivery, and long-term sequelae. Acute infusion-associated toxicities are MAb specific. The anti-CD20 MAbs (rituximab, ibritumomab tiuxetan, and tositumomab) are usually associated with only mild reactions and, in the case of rituximab, tolerance improves with repeated infusions. In contrast, anti-CD45 BC8 MAbs can lead to fever, chills, and mild hypotension (when administered rapidly). The severity of these reactions can usually be reduced by premedication with diphenhydramine, meperidine hydrochloride, or hydrocortisone. The short-term toxicities seen after high-dose RIT for HCT are usually related to myelosuppression. Pancytopenia is an expected consequence and relatively prolonged periods of thrombocytopenia are not atypical. Residual radionuclide in the marrow can potentially pose a toxic risk to newly transplanted marrow cells. To prevent such damage, transplants are usually delayed until the residual radiation in the marrow space is of minimal risk. Press et al. performed the only study to date that delineates the dose-limiting non-hematopoietic toxicities from single-agent RAb therapy [96]. In this study, 27 Gy to the lung was dose limiting, which represents a significantly higher dose than has been tolerated with external-beam TBI (maximum dose 16 Gy). Other short-term toxicities seen with RIT are similar to those associated with external-beam TBI. These include mucositis, nausea, and vomiting. Alopecia is uncommonly seen with high-dose RIT, in contrast to external-beam TBI. Longer term sequelae include hypothyroidism in almost 70% of patients receiving ^{131}I therapy (even when prophylactic potassium iodide is given). Nephropathy was reported in 6 of 93 patients treated with [^{188}Re]anti-CD66 RAb as part of an allogeneic HCT conditioning regimen [140]. In a multivariate comparison of 125 patients who received either high-dose RIT or conventional high-dose therapy with TBI followed by autologous HCT, the long-term risk of therapy-related MDS/AML was between 6 and 7% for both groups, suggesting that no increased risk was associated with the RIT-based regimen [97].

At standard (reduced-intensity) doses, RIT in NHL has a CR rate of ~30% with 20–25% of patients experiencing long-term DFS; therefore, a majority of non-myeloablative RIT patients will ultimately require additional treatment. The impact of RIT on subsequent autologous stem-cell collection has been a subject of interest and concern. In a study by Ansell et al. designed to assess subsequent therapies after [^{90}Y]ibritumomab tiuxetan, a cohort of eight patients were described who underwent PBSC after RIT. One patient in this group required an additional bone marrow harvest to achieve adequate cell counts, but all eight patients engrafted normally [141].

Future directions

Preclinical studies in experimental rodents and primates were instrumental in demonstrating the feasibility and potential efficacy of RIT as a treatment modality [142]. Undoubtedly, preclinical studies remain critical for the development of radioimmunotherapeutic approaches. This research will focus its efforts in several different directions, including the identification of alternative target antigens that demonstrate enhanced efficacy for RIT and also the exploration of alternative radionuclides that offer improved specificity of tumor targeting and lower non-specific toxicities. Other attempts will focus on improving the specificity of radiation delivery and enhancing the tumor penetration with targeted radionuclides.

The number of antigens targeted with RIT may expand significantly over the coming years. Many are under active investigation, including CD22, CD25, CD30, and CD52. For example, even though CD25 has so far not gained major importance for RIT of leukemias [143], it remains an attractive target owing to its relatively selected expression on a high proportion of malignant cells in certain forms of lymphoid neoplasms, including adult T-cell leukemia. Given this expression pattern, α-particle therapy may be particularly appealing in an attempt to spare normal hematopoietic tissue. To this end, a ^{211}At-labeled murine anti-CD25 IgG2a MAb (7G7/B6) has been developed and tested with promising results in immunodeficient mice bearing CD25-positive leukemia and lymphoma cells [144]. Using a similar model, the same group also achieved promising results using a ^{211}At-labeled murine anti-CD30 IgG1 MAb (HeFi-1) in prolonging survival of immunodeficient mice bearing tumors that express CD30, an antigen that is found on some lymphocyte subsets but is also expressed on some lymphoid neoplasms [145]. Together, these findings may set the foundation for progression to clinical studies using ^{211}At-labeled MAbs for the treatment of patients with either CD25- or CD30-expressing leukemias. CD52 is normally expressed on B and T-lymphocytes, monocytes, macrophages, eosinophils, natural killer cells, dendritic cells, and cells of the male reproductive tract [146]. However, CD52 is also expressed by a variety of lymphoid neoplasms and has therefore been exploited as a target for MAb-based therapies, in particular for CLL. Alemtuzumab (Campath-1H), a humanized rat IgG1 MAb directed against CD52, has shown activity alone and in combination with other therapeutics for untreated and previously treated patients with CLL [146–148]. More recently, this MAb has been explored for RIT using ^{188}Re [149]. Preclinical studies found [^{188}Re] alemtuzumab to have good in vitro stability and showed high uptake in blood with biexponential clearance and some increased uptake observed in kidneys and heart [149]. Among the targets explored for treatment of CLL is also CD23. An unconjugated anti-CD23 MAb, lumiliximab (IDEC-152), has shown promising activity in clinical studies [148,150,151] and it is conceivable that this, or other MAbs under development may be used to deliver radiation to tumor sites.

Parallel efforts are ongoing to identify novel radionuclides and radionuclide–antibody conjugates and define their antitumor properties. For example, a ^{213}Bi-labeled anti-CD45 MAb (YAML568) is under preclinical development that shows interesting properties regarding induction of apoptosis and breakage of chemoresistance and radioresistance by overcoming DNA repair mechanisms in leukemia cells [152]. The high LET of ^{213}Bi RIT may also provide synergistic cytotoxic activity when combined with antileukemic chemotherapeutics, for example, for the treatment of CLL [153]. Other examples of radioimmunoconjugates that potentially are exploited in the clinical setting include [^{90}Y]B4, [^{90}Y]BU12 and [^{90}Y] HD37 (mouse IgG1 anti-CD19 MAb), [^{90}Y]RFB4 (mouse IgG1 anti-CD22 MAb), [^{211}At]hTac (humanized anti-CD25 MAb), [^{213}Bi] rituximab (humanized anti-CD20 MAb), and ^{177}Lu-labeled anti-CD20, anti-CD22, and anti-HLA-DR MAbs [154–160].

Clinical data have demonstrated that RAb therapy is capable of delivering 2–4-fold more radiation to target sites than surrounding normal tissues. When patients with relapsed lymphoma receive myeloablative doses of anti-CD20 RIT followed by stem-cell rescue, rates of response have improved dramatically. Objective remissions are seen in 85–90% of such patients, with 75–80% experiencing durable CR, with many lasting 5–18 years [72,96,161,162]. Optimizing the therapeutic index of RIT further by improving biodistribution ratios in favor of target cells may improve outcomes in both hematologic malignancies and solid tumors. A number of pharmaceutical and academic research centers are focusing on the identification of new antigenic targets that are highly expressed on malignant cells and minimally expressed on normal tissues. The increased availability of β-emitting radionuclides with favorable physical characteristics, such as ^{177}Lu and ^{67}Cu, may provide another avenue for future investigations. The α emitters, including those with longer half-lives such as ^{225}Ac, also show great promise [163]. Investigators in Seattle and at the University of Tübingen (Germany) have demonstrated in a canine model that TBI can be entirely replaced with [^{213}Bi]anti-CD45 MAbs in allogeneic reduced-intensity HCT [164].

A number of novel approaches are also being explored to improve the ratio of target to non-target exposure. As noted previously, dose escalation in high-dose RIT for HCT is limited by non-specific irradiation of normal tissues. The cause is both the slow distribution of the RAbs to target cells and the presence of unbound labeled

MAbs persisting in the circulation. One approach, pretargeted RIT, is a process in which patients are initially treated with tumor-reactive MAbs that are not bound to therapeutic radionuclides. This allows localization to tumor sites without subjecting the rest of the body to non-specific irradiation. After maximal accumulation of MAbs in the tumor, a low molecular weight radioactive moiety with high affinity for the tumor-reactive MAbs is administered. Because of its small size, this second reagent rapidly penetrates tumors, where it binds to the pretargeted MAbs. The unbound molecules of the second (radioactive) reagent are small enough to be rapidly cleared from the blood and excreted in the urine within minutes. To improve further the targeted delivery of the radioimmunoconjugate, a clearing agent can be injected shortly before the radiolabeled small molecule to remove unbound MAbs from the bloodstream. The high-affinity binding that occurs between the pretargeted MAbs and subsequently administered radiolabeled small molecule can be achieved through a number of proposed mechanisms. One of the most promising exploits the exceptionally high affinity of avidin for biotin, and another approach employs bispecific MAbs. In animal models, pretargeted RIT has generated therapeutic tumor-to-normal organ ratios of greater than 10:1 (Figure 23.4) and cures have been achieved in 100% of animals with lymphoma and solid tumor xenografts [165,166]. Early patient trials have exhibited similarly encouraging findings in both solid tumors and lymphoma [167–169]. A pretargeted RIT trial for patients with relapsed/refractory AML is ongoing in Seattle.

Nanomaterials also have enormous potential in a wide range of applications associated with HCT. Recently, increased attention has been placed on nanomaterials for this application since the nanostructured surfaces offer a large surface area and greater reactivity, making nanovectors potentially ideal for targeted RIT [170,171]. Nanoparticle materials can be synthetically modified for RIT using well-established techniques after radionuclide loading. Multiple studies over the past decade have been performed to determine the efficacy of nanoparticle carriers for drug delivery (i.e., radiopharmaceutical and chemical). While initial studies determined that blood circulation time and hepatic clearance were primarily dependent on nanoparticle size [170,172,173], a number of more recent studies have shown that there are many factors that determine circulation time and clearance, for example, surface coating and surface charge [171,174–177]. presence of a high immunological protein concentration on the particle surface [178–180], and particle size [171,173,174,181,182]. In fact, the term “stealth particle” has been coined to describe the characteristics necessary in a successful carrier nanoparticle; it should be targeted for delivery of its payload, have a sufficient contact time with the target via an antibody or small molecule, and not be removed by the reticuloendothelial system (RES) so that toxic levels of drug, radiation, or particles are not accumulated in the liver and spleen [170]. To target blood-borne cancer cells, a radiolabeled nanoparticle must have an appropriately long circulation time and have its accumulation in the RES (liver and spleen) and uptake on the bone surfaces slowed sufficiently to maximize therapeutic efficacy and minimize the dose to healthy tissues.

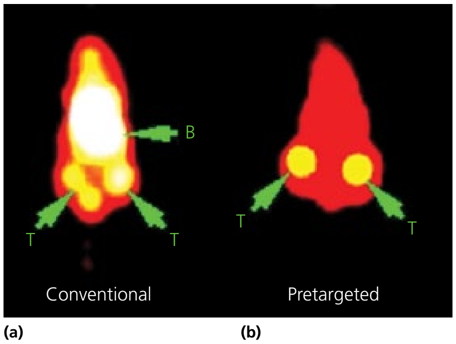

Figure 23.4 Efficacy of pretargeting as demonstrated by planar gamma camera images of Burkitt lymphoma xenograft tumors in athymic mice. Animals were injected with either directly labeled [^{111}In]anti-CD20 Ab (a) or pretargeted with anti-CD20–streptavidin conjugate followed 24 hours later by clearing agent and then by [^{111}In]DOTA–biotin (b). Arrows indicate radioactivity in tumors (T), and blood pool (B) 24 hours after injection of ^{111}In-labeled reagents. Bladder activity is also seen in the conventional mouse. Source: Subbiah K. et al. 2003. Comparison of immunoscintigraphy, efficacy, and toxicity of conventional and pretargeted radioimmunotherapy in CD20-expressing human lymphoma xenografts. *J. Nucl. Med.* 2003; **44**: 437–445. Reproduced with permission of the Society of Nuclear Medicine. (For a color version of this figure, please see the color plate section.)

Extracorporeal adsorption therapy (ECAT) offers another promising means for optimizing biodistribution. In this process, RAbs are injected and allowed 24–48 hours to circulate and distribute to antigen-bearing cells. Then patients undergo a hemodialysis-like procedure during which their blood volume is circulated across an avidin–agarose column. In this way, the biotin-conjugated RAbs that remain in the circulation are removed, thereby minimizing the non-specific radiation to normal organs typically caused by perfusion with blood containing RAbs. In a small safety and efficacy trial conducted in Sweden [183], seven patients with relapsed or refractory B-cell NHL received biotin-conjugated [^{90}Y]rituximab, followed 24–48 hours later by ECAT filtration. The procedure was demonstrated to be safe and effective and ~96% of the unbound [^{90}Y]rituximab-biotin was cleared from the blood.

An exciting new avenue to improve the efficacy of radioimmunoconjugates and potentially reduce non-specific toxicities entails MAb modifications that could allow the clinical use of the Auger electron-emitting radionuclide ^{111}In in combination with anti-CD33 MAb. Specifically, M195 and HuM195 were modified with a 13-mer peptide (CGYGPKKKRKVGG) harboring the nuclear localization sequence of SV-40 large T antigen [184]. This resulted in efficient internalization and improved routing of the radioimmunoconjugate to the nucleus of leukemia cells compared with MAb constructs lacking the nuclear localization sequence. This effect was associated with enhanced killing of drug-sensitive and -resistant AML cell lines and primary AML cells by the radioimmunoconjugates containing nuclear localization sequences [184,185]. An equally exciting avenue to explore is the development of small synthetic multidentate ligands that mimic the properties of MAbs and bind to cell-surface antigens with high affinity and specificity, as shown, for example, for the HLA-DR antigen, and due to the smaller size may provide better tumor penetration [186,187]. Such small engineered molecules may therefore provide an alternative means of targeted delivery of radiation to sites of disease involvement. Finally, an alternative approach to increase accessibility of tumors to radioimmunoconjugates lies in the manipulation of tumor blood flow, and early studies with interleukin-2 suggest that increasing vascular permeability to achieve this goal might be a valid strategy worth exploring in the future [188].

Conclusion

An increasing number of proof-of-principle clinical studies demonstrate that RIT and HCT are safe and feasible and have acceptable toxicities, even in older adults. Research over the last two decades has established important principles of directing RAbs to malignancies, and has provided encouraging results. Nevertheless, RIT is a complex, multidisciplinary effort that still faces many challenges on the road to success; significant obstacles remain that must be overcome to achieve optimal targeting and elimination of target cells by radioimmunoconjugates. For example, the optimal therapeutic radionuclide–antibody–antigen combination for RIT remains unclear, and better controlled clinical trials will ultimately be required to address this question and to determine whether addition of radioimmunoconjugates truly improves patient outcomes over standard treatment. Undoubtedly, future studies will explore alternative antigenic targets and novel radionuclides to improve imaging, dosimetry, and therapy. Furthermore, innovative strategies such as pretargeted RIT and extracorporeal immunoabsorption may optimize the administration of radionuclide therapy and allow more widespread use of very short half-life materials such as the α emitters for RIT. With continued research, RIT holds the potential to establish itself as a radiation boost in combination with other treatments, such as stem-cell rescue, or as adjuvant therapy. Thereby, RIT-based approaches may become an important cornerstone to improve the outcome of patients and will remain an exciting avenue due to constant methodological refinements. It is anticipated that innovations such as those enumerated above will further enhance the feasibility, safety, and efficacy of RIT, with and without HCT.

CHAPTER 24

Documentation of Engraftment and Characterization of Chimerism After Hematopoietic Cell Transplantation

Paul J. Martin
Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Genetic markers in hematopoietic cell transplantation

Marrow cells, growth factor-mobilized apheresis products, and cord blood cells used for hematopoietic cell transplantation (HCT) contain a wide variety of cell types that differ in function and life span. Hematopoietic stem cells (HSCs) in the graft are of central importance for the recovery of marrow function after HCT. With the use of genetic markers, the survival, distribution, and differentiation of engrafted donor cells can be traced throughout the entire life of the recipient. When HSCs are obtained from a syngeneic donor, the only markers that might distinguish donor and recipient cells after HCT are those related to the underlying disease in the recipient. When autologous HSCs are used, genetic markers have sometimes been introduced into the graft in order to demonstrate that the graft contributes to long-term marrow function and to determine whether recurrent malignancy after HCT originated from neoplastic cells that survived the preparative regimen before HCT or from neoplastic cells infused with the graft (see Chapter 8). In allogeneic HCT, donor and recipient cells can be distinguished by testing informative genetic markers.

Informative genetic markers in allogeneic HCT are those that distinguish cells of the donor from those of the recipient, and those that distinguish cells of the recipient from those of the donor. In many cases, the donor and recipient alleles at a single genetic locus will be informative in both directions. For a heterozygous donor with alleles "*a*" and "*b*" and a heterozygous recipient with alleles "*a*" and "*c*," the "*b*" allele is informative for donor-derived cells and the "*c*" allele is informative for recipient-derived cells. In some cases, the alleles at a single locus will not be informative in both directions. For a homozygous donor with the "*a*" allele and a heterozygous recipient with alleles "*a*" and "*c*," the "*c*" allele is informative for recipient cells, but this locus is not informative for donor cells. Evaluation of genetic markers in the donor and recipient before HCT allows loci that are informative to be identified for testing after transplantation.

The probability of finding informative markers depends on the number of loci tested, the number of alleles at each locus, the allele distribution, and the relationship between the donor and recipient. Within members of a family, no more than four alleles can be defined at any single locus, whereas the number of alleles at any given locus in the population can be much larger. For this reason, it is easier to find informative genetic markers with unrelated donors and recipients than with related pairs, but with current molecular biological techniques, markers that distinguish between the donor and recipient can be identified in all patients other than those who have syngeneic donors.

Methods for evaluating chimerism

Historical perspective

In ancient Greek mythology, Chimera was a fearsome three-headed creature – lion at the front, goat in the middle, and serpent at the rear. In today's medical parlance, the term "chimerism" has been used to describe the presence of allogeneic hematopoietic or lymphoid cells in an individual. HCT recipients are sometimes described as having "full chimerism" when all hematopoietic cells and lymphoid cells are derived from an allogeneic donor. The terms "partial chimerism" and "mixed chimerism" are sometimes used when recipient hematopoietic or lymphoid cells persist together with donor cells after HCT. The term "split chimerism" is sometimes used when donor cells are present within some hematopoietic or lymphoid lineages but not in others. The claim that full chimerism has been established must always be qualified by understanding the limits of detection of the assay used to measure chimerism and by defining the hematopoietic and lymphoid lineages encompassed in the test. During the first few weeks after HCT, recipient-derived cells can be found in the blood or marrow of virtually all patients when sensitive tests are used [1,2].

The genetic markers and laboratory methods used for testing chimerism have evolved considerably during the history of HCT. Erythrocyte antigens were among the first markers to be widely used for confirmation of donor-cell engraftment in HCT recipients. Antigens tested for the analysis of chimerism after HCT have included those of the ABO, MN, and Rhesus systems and those of the Kell, Kidd, Duffy, Lutheran, Ss, and P systems. With assays for a wide variety of erythrocyte antigens, informative donor and recipient markers can be identified in more than 80% of sibling pairs. Mixed agglutination and flow cytometry assays can detect admixtures with a sensitivity of 0.1–0.5% [3]. Because erythrocytes have a relatively long life span in circulation, assay results can be confounded by transfusions before or after HCT unless precautions are taken to ensure that the HCT donor has a marker distinctive from those of the recipient and all transfusion donors. Although the long life span of erythrocytes makes it difficult to assess the function of the graft in an ongoing manner, this shortcoming can be circumvented by

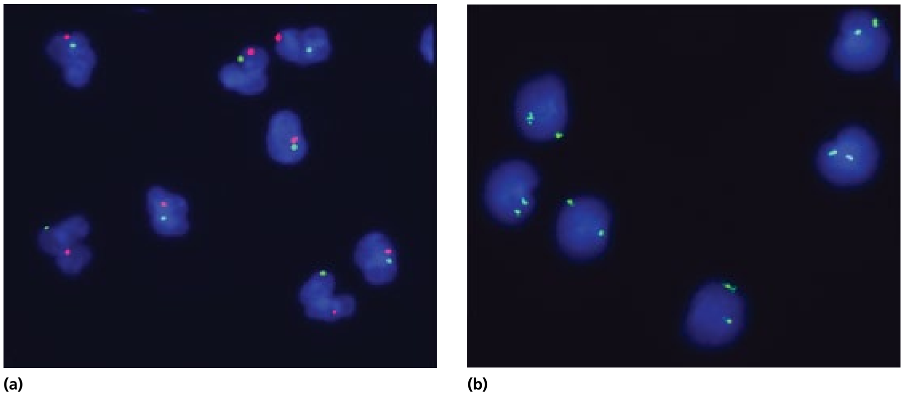

Figure 24.1 Assessment of chimerism in sorted granulocytes (a) and leukemic blasts (b) by dual-color fluorescence in situ hybridization (FISH). Hybridization was carried out with a biotin-labeled Y chromosome-specific DNA probe and a digoxigenin-labeled X chromosome-specific DNA probe. Hybridization was detected with Texas Red-conjugated avidin and fluorescein-conjugated antibody against digoxigenin. Cells were counterstained with 4′,6-diamidino-2-phenylindole (API). Male cells contain a single red fluorescent spot and a single green fluorescent spot, whereas female cells contain two green fluorescent spots and no red fluorescent spots. In this case, granulocytes were derived from a male donor and leukemic blasts were derived from the female recipient. (For a color version of this figure, please see the color plate section.)

assays that define antigens on reticulocytes [3]. Finally, hemolysis caused by ABO incompatibility can delay the appearance of donor erythrocytes in patients who are well engrafted with donor myeloid cells, and results of chimerism studies limited to the erythroid lineage could be misleading.

Conventional cytogenetic analysis of metaphase chromosomes was historically well established as a method for evaluating chimerism in the blood and marrow after allogeneic HCT. Gender disparity between the donor and recipient allows sex chromosomes to be used as convenient genetic markers [4]. In some cases, a constitutional structural rearrangement or heteromorphism can be used as a genetic marker in same-sex pairs. Four major problems limit the applicability of cytogenetic assays for the assessment of chimerism after HCT. First, informative markers are generally not available for same-sex pairs except in cases where a disease-specific cytogenetic abnormality is present in the recipient. Second, techniques for cytogenetic analysis are highly labor intensive and cumbersome. Third, results are limited to cells in metaphase at the time of harvest. Finally, the number of metaphase cells that can be evaluated in any single assay is limited.

During the late 1980s, techniques of molecular biology revolutionized the use of genetic markers in HCT. The two tests most widely used today are in situ hybridization with sex chromosome-specific probes and typing of variable number of tandem repeat (VNTR) or short tandem repeat (STR) polymorphisms by DNA amplification. In situ hybridization permits examination at the level of single cells, but this method is applicable only when the donor and recipient are of opposite sex or when an informative autosomal marker can be identified [5,6]. Informative VNTR/STR polymorphisms can be identified in virtually all allogeneic donor–recipient pairs, but testing at the level of single cells is not possible. Both methods have high sensitivity and specificity, and both methods can provide quantitative results. Both methods can be adapted easily for use in clinical laboratories, and both can be used for evaluating archival specimens.

Molecular cytogenetics

Molecular cytogenetic techniques have many advantages over conventional cytogenetic analysis of metaphase chromosomes. Techniques for in situ hybridization are simple and highly time efficient, and the analysis can be applied equivalently for interphase and metaphase cells [7,8]. Techniques are sufficiently flexible to allow the simultaneous determination of genotype and morphology or surface-marker expression in single cells [7–9]. Large numbers of cells can be analyzed, allowing high precision and sensitivity.

Initial reports of molecular cytogenetic techniques for chimerism testing described the use of a human Y chromosome-specific repetitive DNA sequence probe for fluorescence in situ hybridization [1,10,11]. The upper limit of false-negative results in males was 5.6% and the upper limit of false-positives in females was 2.7% [1]. Age-associated loss of the Y chromosome in cells from older males [12], Y chromosome loss associated with the tumor cell karyotype, and constitutional variation in the Y chromosome DNA probe target sequences are potential limitations of the assay. These limitations make it essential to test specimens either by conventional cytogenetics or by in situ hybridization before HCT to ensure Y chromosome integrity. Cells that show no signal with the use of a Y chromosome-specific probe are inferred to be of female origin. The absence of signal with a Y chromosome-specific probe could result from technical errors that prevent hybridization. This potential problem can be avoided by the use of a mixture of X and Y chromosome-specific probes each labeled with a different chromophore to allow dual-color detection (Figures 24.1 and 24.2). With these reagents, the upper limit of false-positive XX cells in males was 0.63% and the upper limit of false-positive XY cells in females was 0.30% [13]. Chimerism in sex-matched donor–recipient pairs can be analyzed by in situ hybridization with the use of probes for informative deletion polymorphisms [5,6].

VNTR and STR polymorphisms

Certain core DNA sequences are repeated in tandem in the genome, and the number of such tandem repeats (TRs) at any given locus varies among different individuals (Figures 24.3 and 24.4 [14,15]). VNTR sequences are comprised of “minisatellite” cores 8–50 base pairs in length [16], whereas STR sequences are comprised of “microsatellite” cores 2–8 base pairs in length (e.g. CACACA and complementary GTGTGT) [17,18]. Polymorphisms in the number of tandem repeated core sequences within a locus are inherited as codominant Mendelian traits. A large number of loci are available

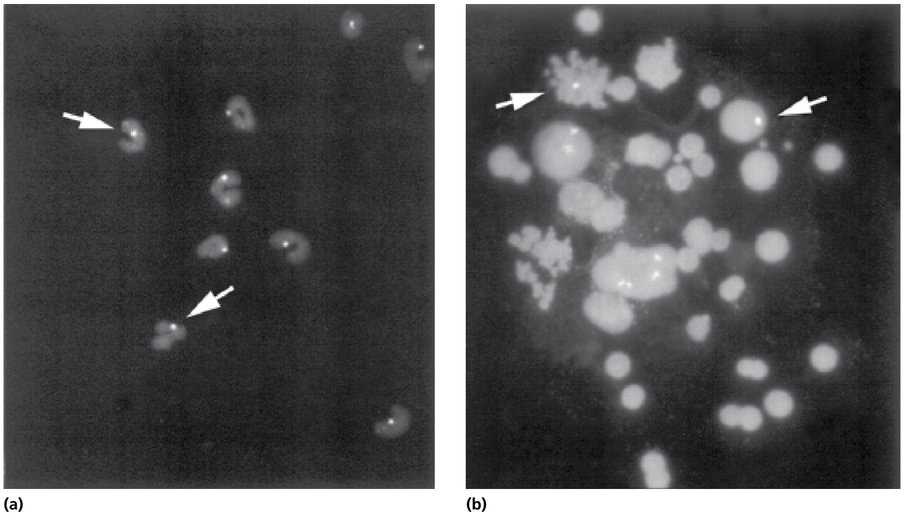

Figure 24.2 Assessment of chimerism by fluorescence in situ hybridization (FISH). A biotinylated Y chromosome-specific DNA probe was hybridized to interphase and metaphase cells obtained from peripheral blood. Hybridization was detected with fluorescein-conjugated avidin, and cells were counterstained with propidium iodide. A fluorescent spot (arrows) is seen in male interphase cells and on the Y chromosome in metaphase cells. Female cells show no hybridization. Granulocytes (a) and phytohemagglutinin (PHA)-stimulated mononuclear cells (b) are shown from a female patient after T-cell-depleted marrow transplantation from a male donor. Granulocytes originated entirely from the donor, whereas mononuclear cells and PHA blasts originated from both the donor and the recipient.

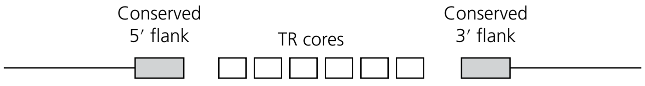

Figure 24.3 Variable number of tandem repeat (TR)/short TR structure. Alleles reflecting differences in the number of TRs can be distinguished by the length of fragments generated after DNA amplification with 5′ and 3′ primers specific for conserved sequences flanking the TR core region.

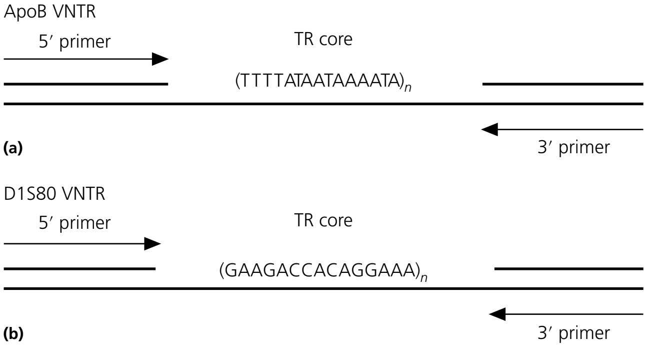

Figure 24.4 Representative TR core sequences for (a) the apoB locus [15] and (b) the D1S80 locus [14]. Arrows show the position of primers complementary to conserved sequences flanking the TR regions. Core sequences at each locus show some heterogeneity resulting from base substitutions, insertions, or deletions.

for testing, and certain loci have more than 25 alleles [7,8,19]. Informative donor and recipient markers can be identified in virtually all allogeneic sibling pairs with a panel of as few as six loci.

VNTR/STR polymorphisms can be identified most conveniently by using the polymerase chain reaction (PCR) to amplify defined segments of DNA [15,20]. In these assays, oligonucleotides complementary to non-polymorphic 5′ and 3′ sequences on opposite strands flanking the polymorphic VNTR/STR core (Figure 24.3) are used to prime DNA synthesis through repeated cycles of denaturing, primer annealing, and heat-stable polymerase-mediated extension. When the two primer binding sites are spaced within a short distance of each other, each cycle of extension creates a primer-binding site for initiation of opposite strand synthesis in the next cycle. The 10^6–10^9-fold amplification of donor- and recipient-derived DNA during the reaction allows fragment length to be analyzed directly by staining with ethidium bromide or silver. With the use of fluorescent primers, reaction products can be visualized by a DNA sequencer or by capillary gel electrophoresis [7,8,21–24] (Figures 24.5 and 24.6 [25]). Efficiency can be improved by simultaneous amplification of different loci in a single "multiplex" reaction [7,8,22,23]. The ability of a multiplex reaction to amplify several loci simultaneously circumvents the need to identify informative loci before testing is carried out, but donor samples and recipient samples obtained before HCT are still needed for the interpretation of results. The multiplex reaction should be designed to amplify selected loci that are most likely to be heterozygous and therefore, informative in a given population [26].

The use of DNA amplification allows chimerism testing with extremely small amounts of starting material, a major advantage when attempting to analyze samples from patients with graft failure and severe leukopenia. Depending on fragment length and the efficiency of amplification, the sensitivity for detecting admixtures is 1–5% and can approach 0.1% in certain cases. Methods involving DNA amplification can be confounded by contamination, which can be recognized when the DNA has originated from an individual other than the donor or recipient. Concurrent amplification of control samples obtained from the donor and recipient before HCT together with the test sample after HCT generally allows unambiguous identification of donor-specific and recipient-specific reaction products and avoids confusion that could be caused by background bands. With the inclusion of standards, assays can be adapted for quantitative determination. Assay results can be affected when alleles have large differences in base-pair length, since shorter alleles may be preferentially amplified [27]. Assay results can also be affected by technical artifacts such as stutter peaks that reflect

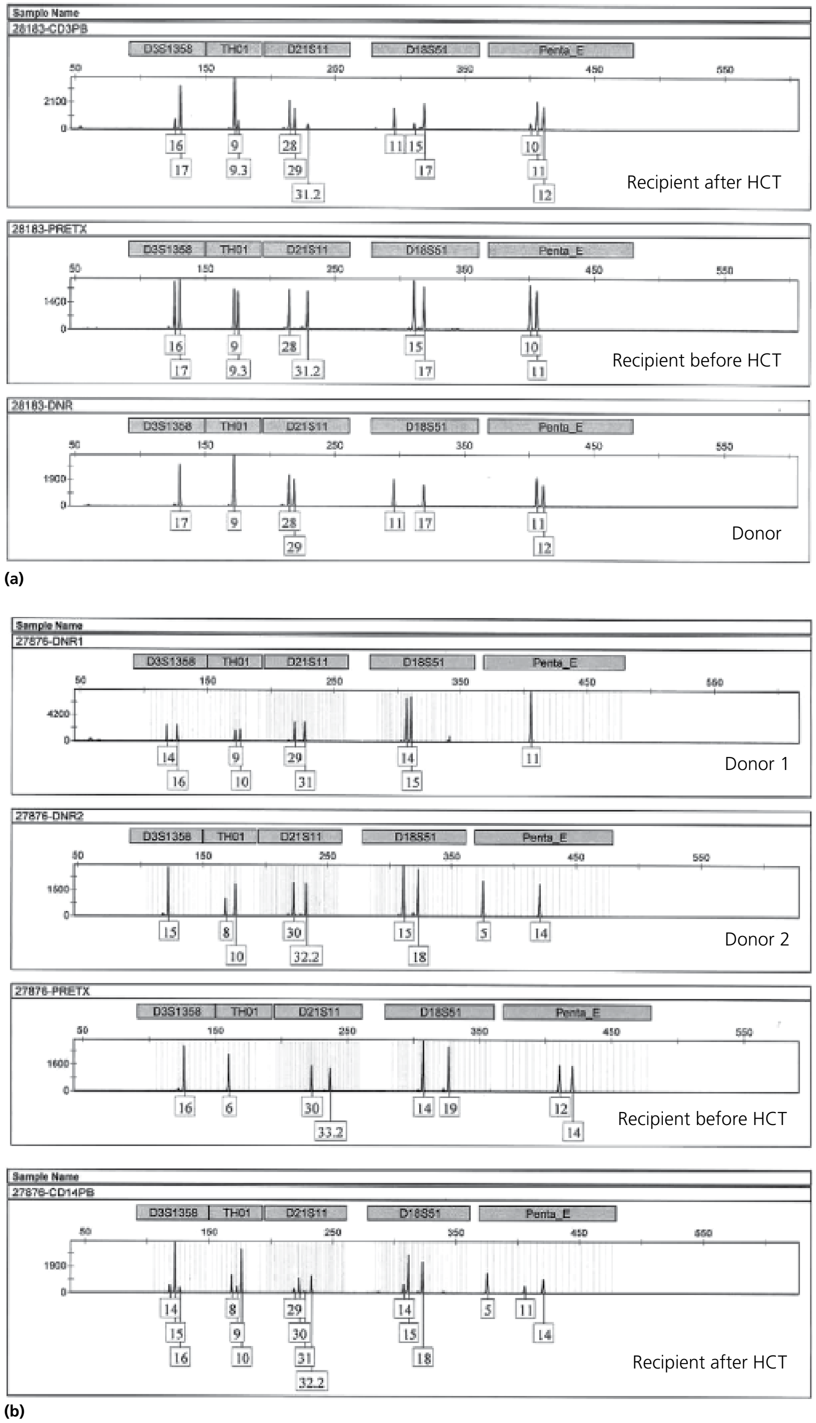

Figure 24.5 Assessment of chimerism by testing short tandem repeat (STR) polymorphisms. (a) Mixed chimerism in CD3$^+$ blood cells tested at 1 year after HCT with a reduced-intensity conditioning regimen for treatment of acute myeloid leukemia. The figure shows capillary gel electrophoresis chromatograms of products after multiplex amplification of five loci (listed in the gray bars) with samples from the donor (bottom), recipient before HCT (middle), and recipient after HCT (top). Allele designations are numbered in boxes below each chromatogram. In this case, informative donor markers include D21S11 allele 29, D18S51 allele 11, and Penta E allele 12. Informative recipient markers include D3S1358 allele 16, TH01 allele 9.3, D21S11 allele 31.2, D18S51 allele 15, and Penta E allele 10. The percentage of donor DNA was calculated according to the height of informative donor peaks divided by the sum of the heights of all informative donor and recipient peaks at each locus. The percentage of donor DNA can also be calculated according to the areas under the respective peaks. The median percentage of donor-derived DNA among values for all informative loci in this specimen was 75%.
(b) Engraftment with two different cord blood units. The sample obtained from the recipient after HCT represented CD14$^+$ monocytes isolated by immunofluorescent staining and flow cytometry. The figure shows chromatograms from each of the two donors (top two profiles), the recipient before HCT (third from top), and the recipient after HCT (bottom). Informative recipient alleles (TH01 allele 6, D18S51 allele 19, and Penta E allele 12) were not detected in the sample from the recipient after HCT. The bottom profile shows that 20% of the sample was derived from one cord blood unit and 80% was derived from the other cord blood unit.

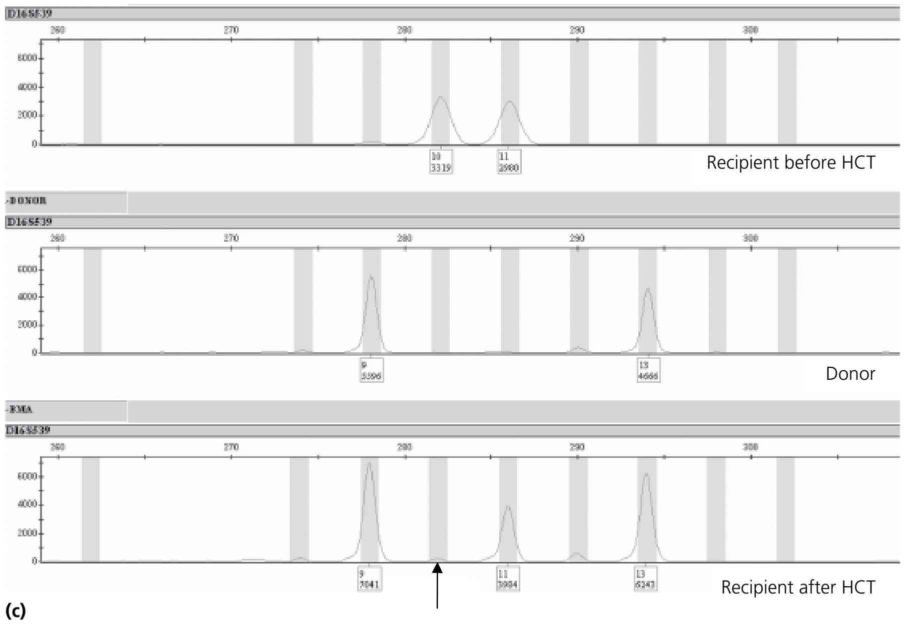

Figure 24.5 (*continued*) (c) Missing allele caused by chromosomal deletion in a patient with multiple myeloma. The figure shows chromatograms of products after amplification of the D16S539 locus from the donor (middle), recipient before HCT (top), and recipient after HCT (bottom). The sample from the recipient after HCT was a marrow aspirate obtained on day 497 after HCT. Both donor peaks (alleles 9 and 13) and both recipient peaks (alleles 10 and 11) are informative. Vertical gray bars across each profile indicate the expected positions of D16S539 alleles. The small peak corresponding to allele 9 in the recipient profile before HCT and the small peaks corresponding to alleles 12 and 8 in the donor profile are artifacts termed "stutter fragments" that contain one less repeat than the normal allele. The marrow sample from the recipient after HCT shows a reduced amount of allele 10 (arrow) compared with allele 11. This imbalance resulted from loss of one chromosome 16 in myeloma cells that persisted after HCT.

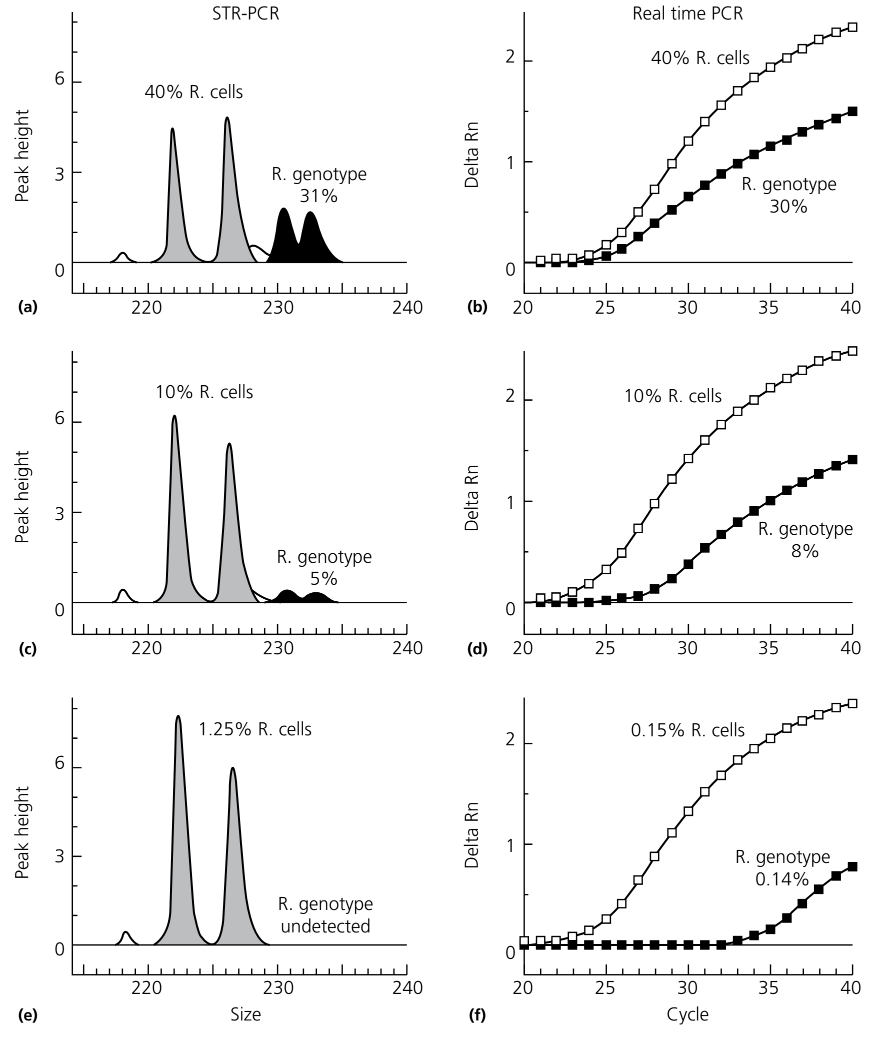

Figure 24.6 Comparison of short tandem repeat polymerase chain reaction (STR-PCR) and real-time PCR chimerism assays. Mixtures contained 40% (a and b), 10% (c and d), 1.25% (e) or 0.15% (f) "recipient" cells. In this case, the D21S11 STR alleles of the recipient (black peaks) were longer than those of the recipient (gray peaks) (a and c). This STR-PCR assay was able to detect the presence of 40% or 10% recipient cells (a and c), but 1.25% recipient cells could not be detected (e). Preferential amplification of shorter alleles is characteristic of STR-PCR assays, which explains the under-representation of recipient alleles (a and c). Donor and recipient alleles were tested individually in separate real-time assays (b, d, and f). The increase in fluorescence indicates the accumulation of amplification products as the reaction progresses from one cycle to the next. With decreasing amounts of the recipient S09a allele, fluorescence exceeds the threshold of detection (horizontal line) at progressively later cycles, shifting the curve to the right. With increasing amounts of the donor S 09b allele, fluorescence exceeds the threshold of detection earlier, shifting the curve slightly to the left. The real-time assay was easily able to detect 0.15% recipient DNA (f). Source: Alizadeh et al. 2002 [25]. Reproduced with permission of the American Society of Hematology.

amplification products containing one less repeat than the normal allele (Figure 24.5) [27]. Accuracy may be improved by averaging results from all informative loci in a multiplex reaction [27]. Nomenclature for describing assay results has been proposed [28], and computer software is available for analyzing and summarizing the results [27].

DNA amplification of other loci for assessment of chimerism

With amplification of certain Y chromosome-specific sequences, sensitivity for detection of male cells in female recipients can approach 0.01% [29,30]. Loci with biallelic polymorphism not involving VNTR/STRs have also been used for quantitative and highly sensitive measurements of chimerism. Two different approaches have been used for these assays. The first involves the use of oligonucleotide primers specific for single nucleotide polymorphisms or short two-base-pair insertions or deletions that differ between the donor and recipient [25,31,32]. Assay conditions are carefully controlled so that the primer binds to only one of the alleles, thereby allowing selective amplification of an informative donor or recipient allele. The second involves the use of oligonucleotide primers that are specific for longer insertion or deletion polymorphisms or null alleles that differ between the donor and recipient [33]. Informative single nucleotide markers or short insertion or deletion markers were identified for more than 90% of related donor–recipient pairs by testing 7–11 biallelic loci [25], and at least one recipient-informative marker was identified in approximately 80% of related donor–recipient pairs by testing 10 loci with longer insertions or deletions or null alleles [33].

Unlike assays with VNTR/STR loci in which amplification products from both donor and recipient DNA are measured simultaneously at the end of the reaction, assays with these loci measure amplification products from DNA of either the donor or the recipient in real time as they accumulate during the reaction in comparison with known standards. Real-time quantitative DNA amplification assays had 0.01–0.1% sensitivity (Figure 24.6).

Clinical application of chimerism tests

Samples used for chimerism testing

Alleles that are informative for the donor and recipient must be identified before samples from the recipient can be tested for chimerism after HCT. This identification can be easily accomplished by testing blood cells from the donor and recipient before HCT. When a recipient sample obtained before HCT is not available, material from a buccal scraping, hair follicle or skin biopsy can be used to identify recipient alleles [34]. Buccal scrapings and mouthwash specimens contain large numbers of cells that originate from the blood and cannot be used reliably to identify recipient alleles after HCT [35].

Cells from blood or marrow are most frequently used for clinical chimerism testing. In most circumstances, results from testing blood cells can provide the necessary clinical information. One exception is the detection of minimal residual disease when malignant cells infiltrate the marrow but are not found in the circulation. Selected lineage-specific populations of interest can be isolated by flow cytometry in order to improve diagnostic accuracy and sensitivity for detecting small numbers of recipient- or donor-derived cells [8,36–38]. For example, separation of blood samples into T-lymphocyte and granulocyte fractions can be very helpful in interpreting results in patients who have received a reduced-intensity conditioning regimen [36,37,39]. Likewise, the diagnosis of recurrent malignancy can be confirmed by demonstrating that a small population of cells with an aberrant cell surface phenotype originated from the recipient [40,41]. Chimerism testing with isolated cell populations is particularly helpful in confirming the diagnosis of recurrent malignancy when the aberrant population represents less than 1% of the sample and when the aberrant phenotype detected after HCT resembles a normal pattern of hematopoietic regeneration or differs from the original malignant phenotype.

General principles

Chimerism tests have been used for a variety of purposes in human HCT (Table 24.1). With sufficiently sensitive assays, recipient cells have been shown to persist for longer than 2 years in most patients after treatment with a myeloablative conditioning regimen [2]. A complex interplay between prior intensive chemotherapy, the intensity of the conditioning regimen before HCT, the number of HSCs in the graft, the immunosuppressive regimen after HCT, and the effects of donor T cells in the graft governs the ability of recipient-derived lymphoid and hematopoietic cells to survive after HCT (see Chapter 9). In general, prior intensive chemotherapy and more intensive conditioning regimens would be expected to decrease the persistence of recipient cells after HCT, whereas higher numbers of HSCs in the graft and the occurrence of acute graft-versus-host disease (GVHD) would be expected to accelerate engraftment [11,42–45]. Given the critical role of donor T cells in helping to eliminate recipient lymphoid and hematopoietic cells that survive the conditioning regimen, depletion of donor T cells would generally be expected to increase the incidence of mixed chimerism after HCT [1,19,44,46]. In some studies, disappearance of recipient cells within the first 100 days after HCT has been associated with an increased incidence of acute and chronic GVHD [47], whereas persistence of recipient cells at 2–6 months after HCT with myeloablative conditioning has been associated with an increased risk of recurrent malignancy [48] or decreased risks of chronic GVHD and overall mortality [49].

General recommendations for chimerism testing after allogeneic HSC have been published [37]. Before individual applications of chimerism testing are discussed in detail, several points should be emphasized:

1 The clinical context weighs heavily in the interpretation of chimerism test results. For example, the absence of donor cells in patients with marrow aplasia could indicate rejection, but a similar absence of detectable donor cells in the non-fractionated marrow

Table 24.1 Clinical applications of chimerism tests in hematopoietic cell transplantation

1. Routine documentation of donor-cell engraftment
2. Evaluate the persistence of donor cells in:
   a. Patients with inadequate marrow function
   b. Patients who are candidates for donor lymphocyte infusion
   c. Patients who are candidates for a second allogeneic transplant
   d. Long-term follow-up patients who are at increased risk of occult rejection
3. Assess the prognostic risks of graft-versus-host disease (GVHD), rejection, or recurrent malignancy
4. Define whether recurrent malignancy or lymphoproliferative syndrome has originated from donor or recipient cells
5. Identify maternal cells in pretransplant patients with severe combined immunodeficiency
6. Correlate immune reconstitution with engraftment after transplantation for treatment of severe combined immunodeficiency
7. Determine whether cells from a transfusion donor can be implicated in causing GVHD
8. Verify the genetic identity of twins
9. Identify the origins of engraftment after HCT with multiple cord blood units

or blood of a patient with florid leukemia relapse could be caused by an overwhelming preponderance of recipient cells.

2 Test results are reported as a ratio in which changes in the numbers of donor and recipient cells can occur independently. Thus, an increase in the proportion of donor cells can be caused both by an increase in the number of donor cells and by a decrease in the number of recipient cells.

3 The interpretation of results depends on an awareness of the types of cell tested in the assay. For example, blood mononuclear cells can include T- and B-lymphocytes, monocytes, immature myeloid precursors, and leukemic blasts. More informative results can be obtained by analyzing purified cell populations.

4 The presence of a particular cell population does not allow direct inferences concerning its functional capabilities or effects. For example, the detection of recipient T cells after HCT does not necessarily indicate that rejection is likely to occur.

5 The inability to detect a particular cell population does not necessarily indicate its absence. The interpretation of test results must always be made with an understanding of the assay sensitivity.

6 Time trends are often more informative than test results at a single time point. For example, the presence of 5% recipient cells at day 28 after HCT might have no clinical significance in itself, but a progressive increase in the proportion of recipient cells could herald rejection or recurrent leukemia.

7 Abnormalities within a single patient can have multiple causes. Thus, the inability to detect donor cells after HCT could indicate the occurrence of both rejection and recurrent malignancy.

8 The inability to detect recipient markers after HCT could result from the absence of recipient cells or from chromosome loss or deletion in malignant cells (Figure 24.5).

9 In the absence of a clinical trial, routine chimerism testing is not needed after HCT with myeloablative conditioning regimens. Chimerism testing may be indicated if patients have evidence of graft failure or recurrent malignancy.

Chimerism testing in patients at risk for graft failure

Although chimerism tests can be carried out for routine monitoring of donor-cell engraftment after HCT [50], the results are of greatest importance in patients who have inadequate marrow function and in patients who might be candidates for donor lymphocyte infusion or a second HCT from the same donor. Marrow graft rejection is usually defined by the absence of donor cells in a patient with pancytopenia and reduced marrow cellularity, but "occult" rejection and complete reconstitution with recipient cells can occur, especially in patients who have received a reduced-intensity conditioning regimen and in patients with chronic myelogenous leukemia (CML) [51]. As noted, the presence of donor cells can be obscured by a florid leukemia relapse or by a malignant population with myelosuppressive effects. Testing the origin of mature T cells can be helpful in excluding rejection in this situation since these cells are not usually affected by recurrent malignancy.

Diagnostic assessments of chimerism test results are especially difficult in patients with poor marrow function. The presence of recipient cells in the blood or marrow does not necessarily indicate that rejection is the cause of poor marrow function since recipient cells are frequently identified early after HCT in patients with normal marrow function [1,2]. Thus, a patient with "benign" mixed chimerism [30] could have poor marrow function because of drug toxicity, viral infection, or a possible marrow stromal defect. Likewise, the inability to detect recipient cells in any single test does not eliminate rejection or occult recurrent malignancy as a possible cause of poor marrow function. In these situations, serial testing can be highly informative.

In patients who are candidates for donor lymphocyte infusions as treatment for recurrent malignancy (see Chapter 70), the detection of persisting donor cells by chimerism tests offers reassurance that rejection has not occurred. In addition, the risk of transient or irreversible aplasia after donor lymphocyte infusion may be much higher in patients with a low proportion of donor cells in the blood or marrow compared with those with a high proportion of donor cells in the blood or marrow [52]. In patients who are candidates for a second HCT from the original donor, the persistence of donor cells indicates that the recipient is still tolerant of donor cells. In this situation, the risk of rejection after a second HCT is negligible, and the preparative regimen can be designed for the sole purpose of eliminating malignant cells.

Serial monitoring of chimerism can be used to monitor initial engraftment after HCT for the treatment of severe aplastic anemia or thalassemia. Mixed chimerism has been associated with an increased risk of rejection in patients with thalassemia [53] and other non-malignant diseases [54]. The presence of less than 5% donor cells in the blood was associated with irreversible graft loss after cord blood transplantation [55]. In some cases, infusion of donor lymphocytes might prevent rejection in patients with decreasing chimerism after HCT [56]. Late "occult" rejection and complete hematopoietic reconstitution with recipient cells have been observed in long-term follow-up after HCT for the treatment of aplastic anemia [57]. This distinctly unusual outcome is of biologic interest but probably has no medical significance except for theoretical concerns that aplastic anemia might recur or that myelodysplasia might develop in the future.

Chimerism testing in patients at risk for recurrent malignancy

In certain circumstances, chimerism tests can be useful in predicting recurrent malignancy after HCT. Findings that demonstrate an increasing proportion of recipient-derived cells in the blood or marrow after HCT can unquestionably herald relapse [19,38,58–62]. By itself, stable mixed chimerism in non-fractionated blood or marrow cells does not predict recurrent malignancy [63,64], although persistence of recipient cells within the CD19$^+$ population has been correlated with an increased risk of relapse in patients with pre-B lineage acute lymphoblastic leukemia [65]. Chimerism testing to demonstrate the recipient origin of isolated cell populations with an aberrant expression of cell-surface antigens can facilitate the early detection of recurrent leukemia [40,41] (Table 24.2). The presence of malignant cells can also be inferred when quantitative STR assays show loss or gain mutations associated with the original disease [66].

In patients with malignant diseases that have aberrant expression of cell-surface antigens, a more direct and unambiguous measure of minimal residual disease can come from flow cytometry or molecular diagnostics, as opposed to chimerism testing (see Chapter 25). Highly sensitive tests and very frequent monitoring would likely be necessary to gain early warning of impending relapse in patients with rapidly progressive diseases such as acute leukemia [50,67]. In several studies, selected patients with increasing levels of mixed chimerism have had immunosuppressive medications withdrawn or have received donor lymphocyte infusions in an effort to prevent recurrent malignancy after HCT [60,61,67–70]. In some cases, patients who had such interventions survived longer than those

Table 24.2 Testing of isolated cell populations by single- or dual-color fluorescence in situ hybridization (FISH) to detect recurrent leukemia

Sample	Percent in original sample	Genotype (%)			
		Y	XY	XX	X
Unsorted marrow		98.5			
Granulocytes	89.0		100.0	0.0	
Lymphocytes	1.6		97.7	0.3	
Blasts	0.2		2.0	86.9	11.1

Single-color FISH with a Y chromosome-specific probe on day 45 after the transplant did not detect an appreciable population of female recipient cells in unsorted marrow from this patient. Granulocytes were isolated by flow sorting of cells with high side scatter characteristics and low expression of CD45, and lymphocytes were isolated by sorting cells with low side scatter characteristics and high expression of CD45. A small population of blasts was isolated by sorting cells with high expression of CD34 and low expression of CD45. Two-color FISH demonstrated that the granulocyte and lymphocyte populations were derived from the male donor, whereas the blasts with aberrant antigen expression were derived from the female recipient. Some of the malignant cells in this patient had a single X chromosome.

who did not have interventions, but bias in the selection of patients for intervention makes these results difficult to interpret. Serial monitoring of chimerism after HCT could offer greater benefit if interventions for treatment of recurrent acute leukemia were more effective [60].

Serial chimerism testing has been useful for early detection of recurrent malignancy in patients with less rapidly progressive diseases such as CML [71] or myeloma [72]. A correlation between persistence of recipient T cells after HCT and an increased risk of recurrent malignancy has been found in patients who received T-cell-depleted marrow for the treatment of CML [73]. The absence of donor T cells in the graft presumably allowed both T cells and malignant HSCs of the recipient to survive after HCT. With the use of a more intensive conditioning regimen before HCT, persistence of recipient lymphocytes after T-cell-depleted HCT was not associated with an increased risk of recurrent CML [74]. The persistence of recipient cells in the blood or marrow during the first 3 months after HCT has not been associated with an increased risk of relapse in patients who received unmodified (T-cell-replete) marrow for the treatment of CML [57]. This result is consistent with earlier findings that the detection of *BCR–ABL* rearrangements in the blood or marrow during the first 3 months after HCT is not associated with an increased risk of relapse [75].

Chimerism testing after reduced-intensity conditioning regimens

A two-stage strategy for HCT involves the initial establishment of mixed chimerism with the use of a reduced-intensity conditioning regimen, combined with potent immunosuppression after HCT to prevent rejection and GVHD. After engraftment has been established, immunosuppression is withdrawn, allowing donor T cells to eliminate residual hematopoietic cells or malignant cells in the recipient through immunological mechanisms (see Chapter 21). In some situations, donor lymphocytes may be infused if withdrawal of immunosuppression does not have the desired clinical effect.

Genetic marker studies and state-of-the-art chimerism tests play an essential part in clinical management with this approach to HCT and in the evaluation of results from these clinical trials. High levels of donor chimerism early after HCT have been associated with improved overall survival and relapse-free survival. Serial testing is likely to be more informative than any single test. In one study, for example, declining proportions of donor cells in the blood or marrow were associated with a high risk of relapse, whereas rising proportions of donor cells were associated with a low risk of relapse [76]. Results of serial monitoring have suggested that full donor T-cell engraftment precedes the development of full donor myeloid engraftment, GVHD, and antitumor effects [37,39,77]. Chimerism tests after reduced-intensity conditioning showed that low levels of donor T-cell and natural killer-cell engraftment at early time points after HCT were associated with an increased risk of rejection and the absence of antitumor effects, whereas high levels of donor T-cell engraftment were associated with an increased risk of GVHD, and earlier establishment of natural killer-cell chimerism was associated with improved progression-free survival [78,79]. In some cases, a progressive decline in donor-cell engraftment has been reversed by the infusion of donor lymphocytes [37,80]. These results suggest that serial monitoring of donor-cell engraftment can help to determine whether donor lymphocytes should be given pre-emptively in order to prevent rejection (see Chapter 77). In another study, recipient T cells persisted for a longer time after HCT in patients prepared with fludarabine and melphalan as compared with fludarabine and busulfan, but no correlation was found between the onset of complete donor chimerism and the occurrence of acute GVHD or the risk of disease progression after HCT [81]. The contrasting results among these studies emphasize that correlations between chimerism and clinical outcomes after HCT may vary according to the intensity of the conditioning regimen.

Other applications for genetic marker studies

Genetic marker studies have found a variety of other useful applications in HCT. In rare cases, for example, it has been possible to demonstrate that hematologic malignancy after HCT originated in donor cells rather than recipient cells. Chimerism tests allow these unusual cases to be identified for further intensive study, although the mechanisms involved in malignant transformation of donor cells remain obscure. With chimerism tests, it has likewise been possible to assess the involvement of donor- or recipient-derived B-lymphocytes in lymphoproliferative disorders caused by Epstein–Barr virus infection (see Chapter 90).

In rare cases, genetic marker studies have demonstrated that GVHD was caused by the cells from a blood product transfusion or from a solid organ allograft. In HCT recipients, evidence implicating cells of a blood transfusion donor came from tests demonstrating the presence of genetic markers different from those of either the donor or the recipient. In some cases, it has been possible to trace the donor through further testing. The universal practice of irradiating all blood product transfusions should eliminate any risk of transfusion-induced GVHD in HCT recipients.

Chimerism tests can be used to identify the origins of engraftment after HCT with multiple cord blood units (see Chapter 39). In this situation, testing must employ markers that are informative for both the recipient and each of the donors. STR markers are very useful for this purpose, since these loci typically have more than two alleles (Figure 24.5).

An extremely useful clinical application of genetic marker studies in HCT is the assessment of monozygosity in twins. With an identical twin donor, there is no risk of rejection or GVHD and hence no need for immunosuppressive treatment before or after HCT. In this situation, the conditioning regimen before HCT is designed solely to eliminate malignant cells. The alleles of a genetic locus are fully informative in a family study when they allow unambiguous assessment of inheritance, which requires parental heterozygosity and the absence of allele matching between the parents. With human leukocyte antigen-identical twins of the same sex and with identity at three additional unlinked fully informative genetic loci, the probability that the twins are not genetically identical is less than 1:100. With identity at four unlinked fully informative loci in addition to HLA, the probability is less than 1:500, and with identity at five unlinked fully informative loci in addition to HLA, the probability is less than 1:1000 [82].

Biologic insights from genetic marker studies

Beyond the clinical applications described above, genetic marker studies have contributed valuable information towards understanding the biology of HCT. Genetic marker studies have recently emerged as powerful tools in studies of HCT for the treatment of congenital immunodeficiency. Infants with severe combined immunodeficiency syndrome (SCID) often have occult maternal T cells in the circulation. The presence of these cells might require immunosuppression to avoid rejection (see Chapter 73). Important information for understanding immune reconstitution after HCT for the treatment of SCID has been obtained by analyzing the lineage-specific patterns of donor-cell engraftment [83,84].

Results of genetic marker studies have made it clear that clinical resolution of non-malignant diseases can often be achieved without complete donor replacement of the defective recipient lymphohematopoietic system [84]. The need for red cell transfusions in patients with thalassemia can be averted by establishing mixed hematopoietic chimerism with only 25% normal donor cells in the marrow, and stable mixed chimerism can ameliorate the effects of sickle disease [85].

Genetic marker studies after HCT have been used to characterize the diversity of marrow-derived cells throughout the body. From these studies, it is now recognized that marrow-derived cells include not only hematopoietic and lymphoid populations, but also tissue macrophages, Kupffer cells in the liver, Langerhans cells in the skin, dendritic cells in the blood, and microglial cells in the brain [86–90]. The donor origin of tissue macrophages and microglial cells has given impetus to the application of HCT for treatment of certain congenital enzyme deficiency diseases (see Chapter 74). In some studies, small proportions of donor-derived stromal cells and mesenchymal cells have been detected in the marrow [91]. Some investigators have reported that marrow-derived cells can differentiate into mature hepatocytes [92,93], epithelial cells of the gastrointestinal tract [93,94], epithelial and endothelial cells of skin affected by GVHD [95], and hair follicles [96]. Rigorous experiments in mice reconstituted with single HSCs, however, did not show an appreciable contribution of donor cells in the brain, kidney, gut, liver, or muscle, suggesting that transdifferentiation of HSCs is a rare event [97]. The small numbers of donor-derived, non-hematopoietic cells observed after HCT in human recipients could reflect cell fusion events or the progeny of other types of stem cells [98–100].

Conclusion

The origin of marrow and blood cells after HCT can be identified by testing informative genetic markers that distinguish the donor and recipient. Molecular methods for in situ hybridization and DNA amplification have made chimerism tests widely accessible for a variety of clinical applications after HCT. Biologic insights gained from testing genetic markers will continue to guide future progress as new approaches are developed in using HCT for the treatment of malignant and non-malignant diseases.

CHAPTER 25

The Detection and Significance of Minimal Residual Disease

Merav Bar and Jerald P. Radich
Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Introduction

Relapse is the major obstacle to cure in leukemia, and this problem persists despite new chemotherapy regimens, "targeted" molecular therapy, the study of mechanisms of drug resistance, and attempts to leverage immunotherapy against the leukemia clone. Unfortunately, once hematologic relapse occurs, the prospects for achieving a subsequent durable remission (and cure) are slim. One strategy to combat relapse is to detect and treat minimal residual disease (MRD) prior to overt relapse. Over the last two decades, the technology to detect minuscule quantities of leukemia has developed and matured, and there are now ample examples demonstrating the strong association of MRD detection and relapse.

The problem of defining remission and relapse is illustrated in Figure 25.1. At diagnosis, patients may have a leukemia burden of up to 10^{10}–10^{12} cells. Thus, potentially millions of leukemia cells may persist after therapy despite the morphologic appearance of remission. MRD detection may have a number of potential roles in leukemia treatment: (i) as an early measure of disease response, (ii) as a post-therapy prognostic factor to assign patients for optimal consolidation therapy, (iii) for early diagnosis of relapse for initiation of pre-emptive therapy prior to overt relapse, and (iv) as a surrogate end-point in clinical trials to evaluate efficacy of novel therapies.

Methods of MRD detection

The standard approach to evaluate residual leukemia by routine pathologic examination of bone marrow (BM) is limited by the subtle morphologic differences between malignant and normal cells. Fortunately, several techniques can be used to find the "needle in the haystack"; these are summarized in Table 25.1.

Chromosomal assays

Conventional metaphase cytogenetics can detect approximately one leukemia cell in 100 normal cells (denoted here as "10^{-2}" sensitivity) if enough metaphases are analyzed (generally 20 metaphases) [1,2]. Although cytogenetics is the method of choice for screening leukemic samples for risk stratification at diagnosis, these studies are also useful to define early response to induction therapy (cytogenetic remission) or to look for new, unanticipated chromosomal changes during therapy. Of note is that cytogenetics samples cells that divide in culture.

Molecular cytogenetics is the analysis of genomic alterations using fluorescence in situ hybridization (FISH)-based technology. FISH uses chromosome-specific or locus-specific probes to target tumor-specific genetic aberrations in metaphase or interphase cells. FISH is useful for rapidly screening 200–10,000 cells for numerical chromosomal aberrations and has the ability to identify minor abnormal clones that may be unrelated to or associated with early clonal evolution of disease undetected by the conventional karyotypic study. Compared with conventional cytogenetics, the sensitivity of FISH ranges from 10^{-1} to 10^{-3} (depending on the number of probes and number of nuclei scored). The sensitivity of FISH increases on combining it with other special techniques, such as in combination with morphologic or immunohistochemical staining (Figure 25.2) [3–5], on specific flow-sorted cell populations, or by increasing the number of mitotic cells analyzed by hyper-metaphase FISH [6–8].

Flow cytometry assays

Cell surface antigen expression can distinguish malignant from normal cells, as malignant cells often express surface antigens in subtly different patterns compared with normal cells [9]. By using combinations of multiple antibodies, "multiparametric" flow cytometric (MFC) assays uses aberrant antigen expression patterns to "fingerprint" the malignant clone (Figure 25.3). If combinations of several antibodies are used to define the aberrant antigen expression, the sensitivity can reach as low as 10^{-3} or less in experienced hands. This technique has been very useful in acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL), where leukemia blasts frequently have abnormal antigen expression compared with normal hematopoietic cells. The current practice of three- or four-color flow cytometry is quickly evolving to methods that allow seven colors or more.

Polymerase chain reaction (PCR)

The most sensitive approach to detect MRD involves nucleic acid amplification using PCR (Figure 25.4) [10]. In the PCR, a specific genetic lesion target becomes the "fingerprint" of the malignancy in order for PCR-driven reactions to have the desired sensitivity and specificity. Two different techniques are currently used: (i) PCR using genomic DNA for detection of clonal rearrangements of immunoglobulin (Ig) and T-cell receptor (TCR) genes in ALL (sensitivity 10^{-3}–10^{-5}), and (ii) reverse-transcriptase PCR (RT-PCR) for detection of gene rearrangements, mainly fusion gene, transcripts

resulting from chromosomal translocations (sensitivity 10^{-3}–10^{-6}). RT-PCR is usually combined with quantitative PCR methods [real-time quantitative PCR (RQ-PCR)] that allow quantitative detection of gene expression. Overexpressed genes in leukemic cells may be used as a target for MRD detection by RQ-PCR. Gene translocations, such as t(9;22) in chronic myelogenous leukemia (CML), and t(15:17), t(8;21), and inv(16)/t(16;16) found in AML, are straightforward leukemia-specific markers for the detection of MRD [11–17]. In ALL, the most common translocation involves the Philadelphia (Ph^{+}) chromosome; however, around 40–50% of cases of ALL (and AML) have a translocation that can be detected by PCR assays [18]. In ALL, the most used PCR markers involve the leukemia-specific "fingerprints" caused by the immunoglobulin heavy chain (IgH) and TCR rearrangement [19,20]. The sensitivity of PCR ranges from 10^{-4} to 10^{-6}, depending on the specific genetic target.

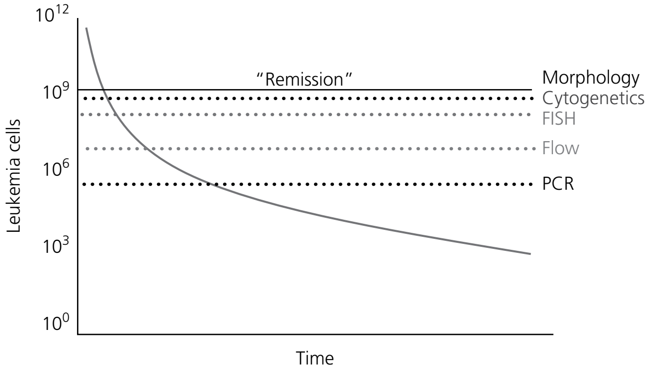

Figure 25.1 The measurement of minimal residual disease (MRD). At diagnosis, there may be as many as 1012 malignant cells present (curved line). After an effective induction therapy that yields a "3-log kill," a huge number of leukemia cells still remain despite morphologic remission. Various techniques can be used to test for MRD as the leukemia burden further lessens with continued therapy. The relative depth of remission plumbed by these techniques is illustrated. FISH, fluorescence in situ hybridization; PCR, polymerase chain reaction.

Since much of the sensitivity is derived from the difference of the genetic target from the background "wild type" genome, it stands to reason that mutations subtly different to normal are more difficult to assay and detect. Thus, point mutations in oncogenes (e.g. N-*ras*) are difficult to assess with great sensitivity with PCR methods. FLT3-ITD mutations are common in AML, but also difficult to adapt to PCR methods, since the composition and length of the insert vary from patient to patient, hence each patient must have custom, "patient-specific" probes, much like Ig VDJ rearrangements in ALL.

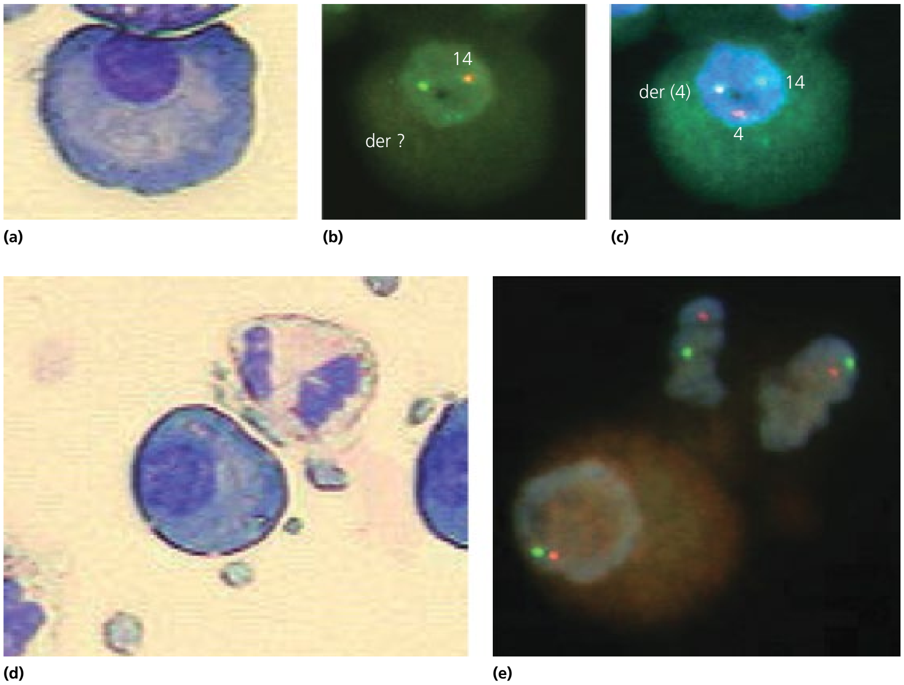
High-throughput sequencing

During the last decade, there has been rapid development of methods to sequence and analyze complete genomes. There are many platforms for high-throughput sequencing (HTS), but most share common steps. First the DNA is fragmented into short single stands, and the DNA is isolated on a bead or in a water–oil emulsion. Each isolated DNA fragment is amplified, and these copies provide the template for a sequencing reaction. Depending on the technology, millions of ~30–250 nucleotide "reads" of sequence are produced. The DNA sequence in total is pieced together by combining the millions of overlapping sequences [21]. Although not yet in routine clinical use, new DNA sequencing technology is bearing down on the clinical laboratory, and is likely to have a major impact on MRD studies in the near future. The technology has the major advantage of being able to uncover all types of genetic lesions – insertions, deletions, translocations, and mutations. In addition, theoretically the sensitivity is limited only by the number of copies of genomes sequenced and by the intrinsic error rate of the DNA polymerases. HTS has been used to detect TCR rearrangements in T-cell ALL after HCT, achieving the sensitivity of detecting a single specific T-cell rearrangement in a background of 100,000 cells [22]. Indeed, in a head-to-head comparison with MFC, it appeared that HTS detected MRD in cases negative by flow cytometry. A similar study of 106 pediatric B-cell ALL demonstrated a sensitivity of 10^{-6}, with high correlation with flow cytometry and gene-specific PCR methods [23]. HTS has been used for MRD monitoring in AML patients with FLT3-ITD or NPM1 mutations [24].

Table 25.1 Common assays used for detection of minimal residual disease (MRD)

Detection method	Target	Sensitivity (%)	Applicability	Comments
Pathologic examination	Cellular morphology	5	Defines CR	Standard clinical practice
Cytogenetics	Chromosome structure	1–5	Upfront risk stratification Response indicator Defines clonal evolution	Assays dividing cells Limited sensitivity
FISH	Specific genetic marker(s)	0.1–5	Leukemia-specific target Rapid assay for known marker	Evaluates single cells Assays all nucleated cells
Combined morphology–FISH or combined IHC–FISH	Specific cell type and specific genetic marker	~0.01–1	Targeting rare event tumor cells Screening stem-cell harvests	Time consuming Requires automation
Flow cytometry	Surface antigen (protein) expression	0.001–0.1	Rapid, quantitative measure of response	Measures single cells Immunophenotypes may shift over time Sensitivity based on number of "colors" and expertise
PCR for chromosome aberrations	mRNA sequence	0.0001–0.1	Diagnosis to detect translocations MRD assessment	Limited to patients with known fusion gene transcripts
PCR for Ig/T-cell receptor genes	DNA sequence (junctional region)	0.001–0.1	MRD assessment	Patient specificity means time consuming at diagnosis but rapid assay at follow-up False negatives may result with clonal evolution or phenotype shifts
High-throughput sequencing	Sequence of large genome fragments	0.0001–0.001	MRD assessment	Not yet in routine clinical use, but transition of new sequencing methods to the clinical laboratory is under way

CR, complete remission; FISH, fluorescence in situ hybridization; IHC-FISH, sequential immunohistochemistry-FISH; PCR, polymerase chain reaction.



Targeted scanning with CD19 monoclonal antibody

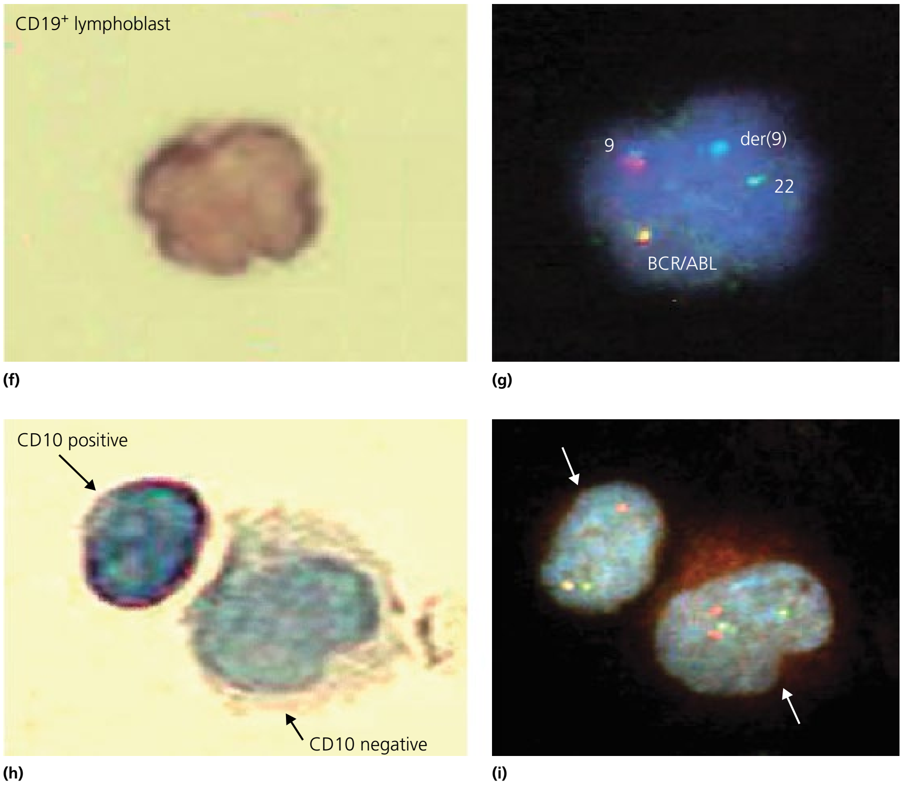


Figure 25.2 Plasma cell-specific fluorescence in situ hybridization (FISH) analysis. (a–e) Cytospin slides are made from the bone marrow aliquot and stained with May–Grünwald stain. After the cells have been mapped to the slide, the slide is destained and hybridized with the selected DNA probe. For details, see [5]. (a) A plasma cell that has been mapped. This same cell is seen in (b), showing a variant immunoglobulin H (*IGH*) pattern using a dual-color *5′IGH/3′IGH* break-apart probe. Once an *IGH* gene rearrangement is found in a patient with multiple myeloma, the same slide is rehybridized to determine its partner chromosome in the IGH translocation. (c) A fusion signal is detected with the *FGFR3* (fibroblast growth factor receptor-3)/*IGH* probe indicating the derivative chromosome 4 of the t(4;14) or der(4)t(4;14). The second fusion that would have indicated the der(14)t(4;14) is not present in this patient, the result of loss of the derivative 14 chromosome. In another slide from this patient [(d) and (e)], monosomy 13 is shown in the neoplastic plasma cells, but the segmented neutrophil adjacent to the plasma cells shows both chromosome 13 signals (one each in each of the segments of the nucleus). The chromosome 13 probe set used was composed of D13S319 probe (red), which maps to 13q14.3, and the *LAMP1* (lysosomal-associated membrane protein-1)/13q34 reference probe labeled in green. Sequential immunohistochemistry (IHC)/FISH is shown in (f)–(i). (f) A CD19^{+} lymphoblast that is *BCR/ABL1* fusion gene positive (g), indicating residual disease and not a hematogone. Similarly, (h) and (i) show the cell that is CD10^{+} is positive for the *BCR/ABL1* fusion gene, and the CD^{-} cell is negative for the *BCR/ABL1* fusion gene. The *BCR/ABL1* probe used for the sequential IHC/FISH studies was the single fusion probe spiked with 9q34/argininosuccinate synthetase gene probe labeled in Spectrum aqua. All probes were obtained and reproduced with permission from Abbott Molecular Inc. (Des Plaines, IL, USA). (For a color version of this figure, please see the color plate section.)

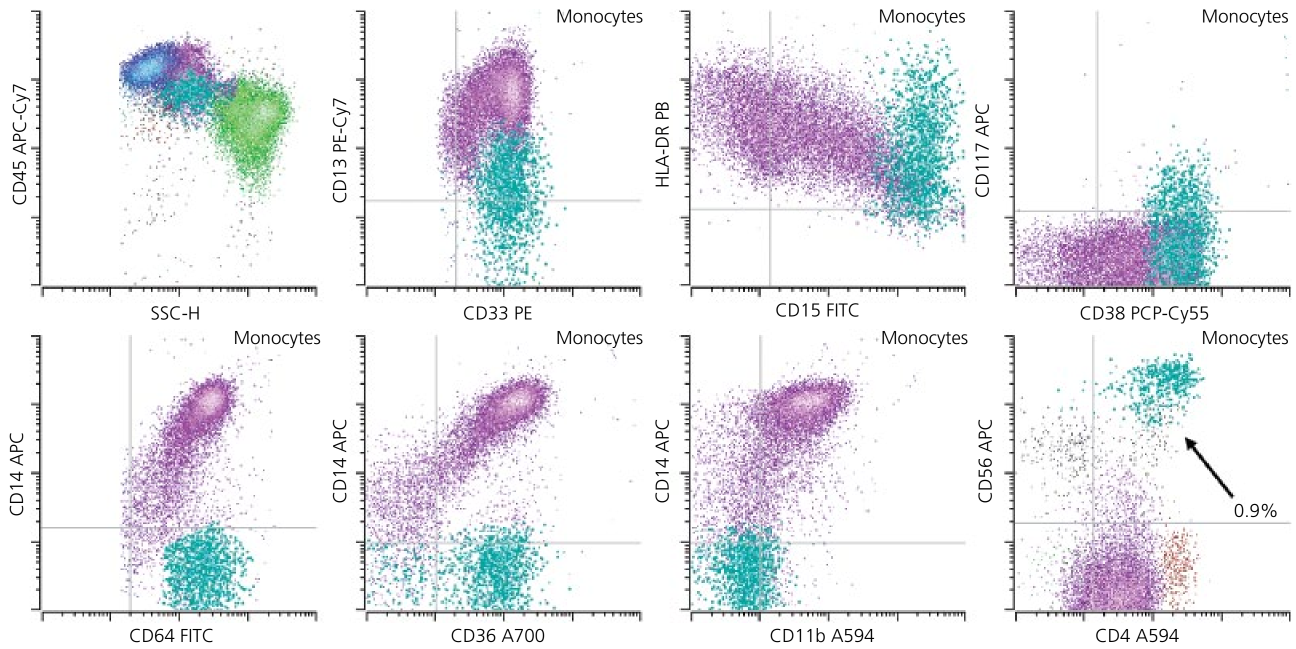

Figure 25.3 Flow cytometry assays for detection of minimal residual disease. Leukemia samples can be labeled with multiple fluorescent antibodies, and cells can be distinguished by the size of the cell and the types of antibody that bind the cell surface. Normal hematopoiesis has very stereotypical cell antigen expression linked to differentiation; leukemia cells are distinguished by inappropriate expression patterns of these antibodies. In the example, a residual acute monocytic leukemia is analyzed with multiple antigens. In the bottom left panel, the sample shows an inappropriate expression of CD56 and CD4 consistent with residual disease. In this example, these cells made up 0.9% of the total nucleated cells. Figure 25.4 Quantitative polymerase chain reaction (PCR). The cartoon shows the principle behind the two most popular quantitative approaches: the Taqman (ABI) and the LightCycler (Roche). In the Taqman reaction (I), the probe is a 5′ reporter dye and a 3′ quencher molecule. When the probe is intact, the quencher blocks laser excitation of the reporter. During PCR, the 5′ exonuclease activity of Taq polymerase releases the reporter, which, free from the quencher, is excited by the laser detection system. In the LightCycler system (II), annealing of juxtaposition probes during PCR synthesis allows for the transfer of resonance energy that can be stimulated by the laser and detected. In both systems, a standard curve is generated that plots dilutions of the standards versus the PCR cycle number at which a threshold signal is obtained (middle panel). The starting amount of target in unknown samples is thus detected by a back-calculation of cycle threshold in the unknown (Ct) against the standard curve. The clinical significance of MRD

Many studies have demonstrated the effect of MRD on relapse and outcome in the setting of conventional chemotherapy and HCT. Detection of MRD after conventional therapy can bring patients to transplant in a timely manner, and detection of MRD after transplant may be used in order to start preemptive antileukemic therapy prior to overt relapse.

MRD detection in acute lymphoblastic leukemia (ALL) patients receiving chemotherapy

In ALL, MRD detection is accomplished by either MFC, PCR, or, more recently, HTS. Flow cytometry assays rely on the unique and aberrant constellation of surface antigens in the leukemia clone. PCR-based assays rely on the clonal IgH (V-D-J) or TCR gene rearrangements that can be used to follow MRD in approximately 70% of ALL cases. This PCR method takes advantage of the unique gene rearrangements that occur in these genes as cells develop into functional B and T cells. While all individual normal B and T cells should have unique gene rearrangements, a clonal outgrowth of malignant cells should all have identical gene rearrangements, and this "fingerprint" can later be used to distinguish malignant versus normal cells in "remission" samples. Although both methods have excellent sensitivity, both are susceptible to clonal "shifts" that occur with disease progression in 10–20% of cases, whereby the relapsing clone appears with a different gene rearrangement or surface antigen pattern than the presenting leukemia [25–28]. The combined use of these two methods should permit MRD monitoring in almost all patients and prevent false-negative results due to clonal evolution and phenotypic shift [29,30]. Based on several prospective clinical trials, detection of MRD has emerged as part of standard evaluation and treatment guidance of both pediatric and adult ALL [31].

The clinical impact of MRD in ALL depends on the time point at which it is assessed. Detection of MRD can be used to evaluate early treatment response, and thereby allows the identification of low- and high-risk patients who may profit from therapy reduction or therapy intensification, respectively. Early clearance of leukemia cells is a favorable prognostic indicator in childhood and adult ALL [19,32–34]. Low or absent MRD in the BM after the completion of induction therapy predicts a favorable outcome, as MRD-negative patients have an overall relapse rate of only 2–10% (Table 25.2) [19,35–38]. On the other hand, high MRD levels at the end of induction treatment have been associated with high relapse rates of 70–100% (Table 25.3) [19,35–37,39]; these patients at risk for relapse may benefit from considering alternative treatment approaches such as transplantation [19,40–42]. MRD status after induction therapy may be the most significant prognostic factor in ALL, independent of other clinically relevant risk factors [19,32,37,43]. In pediatric ALL cases who relapse after achieving remission, MRD status after re-induction treatment is similarly important [41,44]. For example, Coustan-Smith et al. [44] studied

Table 25.2 Minimal residual disease (MRD) studies in childhood acute lymphoblastic leukemia

Study	*N*, diagnosis	MRD method	MRD time point	Impact of MRD on clinical outcome
Cave et al. 1998 [46]	178 (B and T ALL)	Ig/TCR-PCR	After induction therapy and during the first 6 months after complete remission	8% of patients with negative MRD after induction relapsed vs. 38% of patients with positive MRD. The risk of relapse was 7.3 times higher in patients with detectable disease than in those with undetectable disease after consolidation
van Dongen et al. 1998 [47]	240 (B and T ALL)	Ig/TCR-PCR and *TAL1* deletion	Post-induction therapy	MRD-positive was associated with 39–86% relapse rate at 3 years, compared with 3–15% relapse in MRD-negative. Risk of relapse in patients with high-degree MRD early after induction was three times higher than in patients with low-degree MRD. During further follow-up even a low degree of MRD was associated with high relapse rates
Coustan-Smith et al. 2000 [48]	195 (B and T ALL)	Flow cytometry	End of induction and during weeks 14, 32, and 56 of continuation therapy	Detection of MRD was significantly associated with a greater likelihood of relapse. At the end of induction therapy, the 5-year cumulative incidence of relapse was 43% for MRD-positive patients compared with 10% for MRD-negative patients
Dworzak et al. 2002 [49]	108 (B and T ALL)	Flow cytometry	Four time points during the first 6 months of treatment	Presence of MRD at day 33, week 12, and weeks 22–24 was associated with a greater likelihood of relapse, but not at day 15. The MRD level that was associated with increased relapse risk decreased with time under treatment (day 15, ≥1.0%; day 33, ≥0.1%; week 12, ≥0.01%; weeks 22–24, any MRD positivity)
Nyvold et al. 2002 [50]	104 (B and T ALL)	Ig/TCR-PCR	Day15 and day 29 after start of induction therapy	Patients who relapsed had higher day 15 and day 29 MRD levels than patients who stayed in remission (median levels: day 15, 1% versus 0.1%, $p = 0.03$; day 29, 0.4% versus 0.01%, $p = 0.0001$)
Marshall et al. 2003 [51]	85 (B and T ALL; Ph negative)	Ig/TCR-PCR	1, 12, and 24 months from diagnosis	Patients with $\leq 10^{-3}$ residual blasts at 1 month after diagnosis had 81% 5-year RFS compared with 23% for patients with $>10^{-3}$ residual blasts. 5-year RFS for MRD-negative patients at 12 months after diagnosis was 71% vs. 36% for MRD-positive patients; 5-year RFS for MRD-negative patients at 24 months after diagnosis was 74% vs. 36% for MRD-positive patients.
Paganin et al. 2008 [52]	60 (relapsed B and T ALL)	Ig/TCR-PCR	3–5 weeks after initiation of treatment, 6–8 weeks after initiation of treatment, and 9–16 weeks	3-year EFS was 79% for patients with negative MRD at first time point, 43% for patients with low positive MRD and 18% for patients with high positive MRD. The relative risk of relapse for positive MRD patients at the first time point available vs. with negative-MRD patients was 4.4
Van der Velden et al. 2009 [53]	99 (infants with B ALL)	Ig/TCR-PCR, MLL rearrangement	During and after induction, consolidation, and maintenance	51% of patients with high MRD at day 15 relapsed vs. 11% of patients with low MRD. All patients with MRD $\geq 10^{-4}$ during consolidation relapsed. After consolidation, 71% of MRD-positive patients relapsed vs. 17% of MRD-negative patients
Scrideli CA et al. [54]	229	Ig/TCR-PCR	Day 14 and day 28 of induction therapy	5-year EFS was 85% for patients with negative MRD on both day 14 and day 28, 76% for patients with positive MRD on day 14 and negative on day 28, and 28% for patients with positive MRD on both days

Ig/TCR-PCR, immunoglobulin/T-cell receptor polymerase chain reaction.

Table 25.3 Studies examining the impact of minimal residual disease (MRD) on outcome of adult acute leukemia (ALL and AML) in the non-transplant setting

Study	*N*, diagnosis	MRD method	MRD time point	Impact of MRD on clinical outcome
Vidriales et al. 2003 [55]	102 (B and T ALL)	Flow cytometry	Day 35 of induction	Patients with low MRD levels (<0.05%) had a significantly longer RFS than patients with high MRD levels (median RFS: 42 months vs. 16 months)
Brüggemann et al. 2006 [56]	196 (B and T ALL)	Ig/TCR-PCR	Up to 9 time points in the first year after induction	Patients with a rapid MRD decline to lower than 10^{-4} or below detection limit at day 11 and day 24 had a 3-year relapse rate (RR) of 0%. Patients with MRD of 10^{-4} or higher until week 16 had a 3-year RR of 94%. The remaining patients had an RR of 47%
Holowiecki et al. 2008 [57]	116 (B and T ALL)	Flow cytometry	After induction therapy	The incidence of relapse at 3 years was 26% for patients with MRD <0.1% after induction vs. 81% for patients with MRD ≥0.1%
Bassan et al. 2009 [58]	112 (B and T ALL)	RQ-PCR (Ig/TCR and/or fusion genes)	3 time points after initiation of induction	5 year OS/DFS were 75%/72% in the MRD-negative group compared with 33%/0.14% in MRD-positive group. MRD was the most significant risk factor for relapse (HR 5.22)
Patel et al. 2010 [59]	159 (B-ALL)	RQ-PCR (Ig/TCR)	3 time points after initiation of induction	At completion of phase I induction, 5-year RFS was 69% in MRD-negative patients and 42% in MRD-positive patients. At completion of phase II induction, 5-year RFS was 71% in MRD-negative patients and 15% in MRD-positive patients
Gökbuget et al. 2012 [60]	580 (B and T ALL)	RQ-PCR (Ig/TCR)	Day 71 and week 16 after induction	Patients with molecular CR after consolidation had a significantly higher probability of continuous complete remission (74% vs. 35%) and of overall survival (80% vs. 42%) compared with patients with no molecular CR
Pane et al. 2005 [61]	42 B-ALL; Ph+	RT-PCR (*BCR-ABL*)	End of induction and end of consolidation	In patients with good molecular response (>2 log reduction of residual disease after induction and >3 log reduction after consolidation therapy), the probability of RFS, DFS and OS at 2 years was 38, 27, and 48%, respectively, compared with 0, 0, and 0% in patients with poor molecular response
Ottmann et al. 2007 [62]	49 B-ALL; Ph+	Qualitative PCR (*BCR-ABL*)	After end of induction and each consolidation cycle	Median DFS was significantly longer in patients in molecular CR compared with patients with no molecular CR (18.3 vs. 7.2 months)
Yanada et al. 2008 [63]	100 B-ALL; Ph+	RT-PCR (*BCR-ABL*)	Day 28 and day 63 after induction, end of consolidation	Negative MRD at the end of induction therapy was not associated with longer RFS or lower relapse rate. Molecular MRD elevation during hematologic CR is predictive of subsequent relapse, but allogeneic hematopoietic stem-cell transplantation can override its adverse effect (12/13 patients who had not undergone allogeneic HCT experienced a relapse, whereas 10/16 patients who had undergone allogeneic HCT were alive without relapse at a median of 2.9 years after transplantation)
Lee et al. 2009 [64]	52 B-ALL; Ph+	RT-PCR (*BCR-ABL*)	After induction chemotherapy, 1st course TKI, consolidation, 2nd course TKI	No prognostic impact of MRD after induction chemotherapy before TKI. However, a reduction in *BCR-ABL* transcript levels of at least 3 log after the first 4 weeks of imatinib therapy was the most powerful predictor of lower relapse rate (12.1% vs. 45.1%) and better DFS (82.1% vs. 41.7%).
Venditti et al. 2000 [65]	55 (AML)	Flow cytometry	After induction and after consolidation	The most predictive MRD cutoff value after induction was 4.5×10^{-4} cells: 58% of patients with 4.5×10^{-4} cells or more after induction had relapsed, compared with 40% of those with fewer than 4.5×10^{-4} cells. After consolidation, the most predictive MRD cutoff value was 3.5×10^{-4}cells: 77% of these patients had relapsed, compared with 17% patients with lower MRD levels.
Venditti et al. 2002 [66]	63 (AML)	Flow cytometry	After consolidation	81% of MRD-positive patients after consolidation relapsed vs. 27% of MRD-negative patients. MRD positivity at consolidation was associated with a high probability of relapse ($p < 0.00026$) and short duration of RFS ($p = 0.008$).
Kern et al. 2004 [67]	93 (AML)	Flow cytometry	After induction and after consolidation	The degree of disease reduction between diagnosis and CR was significantly related to RFS after both induction ($p = 0.0001$) and consolidation ($p = 0.00008$).
Buccisano et al. 2006 [68]	100 (AML)	Flow cytometry	Several time points after induction and consolidation	Post-consolidation MRD-negative patients had a superior relapse rate, OS and RFS ($p < 0.001$, for all comparisons), regardless of the MRD status after induction
Maurillo et al. 2008 [69]	142 (AML)	Flow cytometry	After consolidation	5-year RFS rates were 60% and 16% for MRD-negative and -positive patients, respectively. 5-year OS rates were 62% and 23%, respectively
Al-Mawali et al. 2009 [70]	54 (AML)	Flow cytometry	After induction and after consolidation	MRD level post-induction influenced RFS ($p = 0.004$) and OS ($p = 0.003$). Multivariate analysis showed that MRD post-induction was a powerful independent prognostic factor for both RFS ($p = 0.037$) and OS ($p = 0.026$)

the clinical significance of MRD in ALL after first relapse using flow cytometry for MRD detection. Of the 35 children with morphologic remission after induction treatment, 19 (54%) had an MRD of 0.01% or more, and their subsequent relapse rate was 70%, compared with 28% for the 16 MRD-negative patients. The value of continuing MRD monitoring during maintenance therapy and off therapy is less clear, since frequent monitoring has been difficult to employ [33,37,45].

There is increasing evidence that in adult ALL, as in children, an early decrease in MRD level after induction therapy is an important predictor of prognosis and response to chemotherapy [55–64,71–73]. Assessment of MRD kinetics at different follow-up time points defined risk groups based on a specific threshold MRD level in standard-risk adult ALL patients [74]. Patients with a rapid MRD decline to lower than 10^{-4} or under the detection limit at day 11 (during first induction) and day 24 (at the end of induction) were at low risk, with a 3-year disease-free survival (DFS) and overall survival (OS) of 100%. In contrast, patients with a persistent MRD of 10^{-4} until week 16 were at high risk, with a 3-year DFS of 5.8% and a 3-year OS of 45.1%.

MRD measurement in the first year of treatment is also a useful outcome predictor for adult T-cell ALL patients [75]. MRD-positive patients prior to consolidation therapy had a probability of relapse at 2 years of 82%, compared with 39% in MRD-negative patients. In a larger study of 102 adolescent and adult ALL patients, MRD at day 35 was found to be the most powerful independent prognostic parameter by multivariate analysis [76]. Patients in morphologic complete remission (CR) and a low MRD level (<0.05%) had a median relapse-free survival (RFS) of 42 months versus 16 months in the case of higher MRD levels. An excellent prognosis with a projected 5-year RFS of 90% was observed when MRD levels at day 14 were very low (<0.03%). The German Multicenter Study Group for Adult ALL evaluated MRD by real-time PCR directed to TCR and Ig gene rearrangements in 580 patients with B- and T-lineage Ph$^-$ ALL with cytologic complete remission (CCR) after induction and consolidation chemotherapy [12]. MRD+ after consolidation chemotherapy had the worst prognostic effect on CCR after 5 years. The probability of CCR after 5 years was 74 ± 3% for patients with MRD– versus 35 ± 5% for patients with MRD+. OS was significantly inferior in MRD+ than in MRD– patients (42 ± 5% vs. 80 ± 3%).

In adult Ph$^+$ ALL, MRD is followed by measuring *BCR-ABL* transcript levels with RQ-PCR [61–64,77,80]. Using this approach, it has been demonstrated that 42 patients with complete hematologic response following induction therapy were divided into two prognostic groups: good molecular responders (with a >2 log reduction of *BCR-ABL* transcript levels after induction, and a >3 log reduction after consolidation therapy was correlated with significantly better 2-year survival (48%) compared with patients with higher MRD levels (0%) [80]. However, in Ph+ ALL patients treated with combinations of tyrosine kinase inhibition and chemotherapy, rapid molecular response alone is not necessarily associated with a favorable prognosis, in that a single observation of elevated MRD is associated with an increased risk relapse [63].

MRD in ALL in the transplant setting

MRD detection prior to and following transplantation is strongly predictive of outcome. Many reports have shown that the MRD burden prior to conditioning is the most powerful single predictive factor for relapse after HCT (Table 25.4) [78,79,81–89]. In these studies, the event-free survival (EFS) for the MRD-negative groups prior to HCT was often more than 70%, whereas for those in the MRD-positive group the EFS fell to 17–50%. Both PCR and flow cytometry were used to detect MRD in these studies, and various criteria have been used to determine "low" from "high" levels of

Table 25.4 Studies examining the impact of pre- or post-hematopoietic cell transplantation minimal residual disease (MRD) levels in ALL and AML on subsequent relapse and transplant outcome

Study	*N*, diagnosis	MRD method	MRD study time point	Impact of MRD on clinical outcome
Knechtli et al. 1998 [78]	64 (ALL)	PCR of Ig or T-cell receptors	~1–12 weeks pre-transplant	2-year EFS for high-level MRD (>10^{-2}), low-level MRD (10^{-3}–10^{-5}), or MRD negative was 0%, 36%, and 73%, respectively
van der Velden et al. 2001 [79]	17 (ALL)	Ig/TCR gene by Southern blotting, PCR heteroduplex analysis, sequencing, and Ig/TCR-PCR	Pre-HCT (no specific time indicated)	2/11 patients with negative MRD relapsed post-transplant compared with 4/6 patients with positive MRD
Uzunel et al. 2001 [81]	30 (ALL)	Ig/TCR-PCR	0–30 days (median 9 days) before HCT	13/25 patients with MRD positivity pre-transplant relapsed post-transplant vs. 0/25 MRD-negative patients.
Bader et al. 2002 [82]	41 (ALL)	PCR amplification of antigen receptor gene rearrangements and clone-specific oligoprobing	Prior to conditioning (no specific time indicated)	5-year EFS was 23%, 48% and 78% for high-level MRD positivity, low-level MRD positivity and negative MRD, respectively
Krejci et al. 2003 [83]	140 (ALL)	Semiquantitative PCR, RQ-PCR, and oligoprobe blotting-based analysis of TCR and Ig gene)	Prior to conditioning (no specific time indicated)	16% of patients with negative MRD relapsed post-transplant compared to 65% of patients with positive MRD.
Sanchez et al. 2002 [84]	24 (ALL)	Flow cytometry	Prior to conditioning (no specific time indicated)	4/6 MRD-positive patients relapsed post-HCT vs. 3/18 MRD-negative patients. 2-year DFS for MRD-positive patients was 33 % vs. 74% for MRD-negative patients.
Uzunel et al. 2003 [85]	32 (ALL)	Ig/TCR gene rearrangement, QR-PCR	Before and after HCT	11/24 patients MRD positive before HCT relapsed vs. 1/5 for MRD-negative patients
Sramkova et al. 2007 [86]	25 (ALL)	Ig/TCR gene rearrangement, QR-PCR	1 week prior to conditioning	6/8 MRD-positive patients relapsed post-HCT vs. 1/17 MRD-negative patients. Multivariate analysis identified pre-transplant MRD as the only significant risk factor for relapse post-HCT
Spinelli et al. 2007 [87]	37 (ALL)	RQ-PCR for fusion chimeric genes and Ig/TCR rearrengements	Prior to conditioning (no specific time indicated)	3-year overall survival for MRD-negative patients was 80% vs. 49% for MRD-positive patients. The cumulative incidence of relapse was 0% and 46%, respectively.
Bader et al. 2009 [88]	91 (ALL)	Ig/TCR gene rearrangement, QR-PCR	1–39 (median 13) days before conditioning	Probability of EFS and cumulative incidence of relapse in MRD-positive patients was 27% and 57% vs. 60% and 13% in MRD-negative patients.
Leung et al. 2012 [90]	122 (ALL, AML)	Flow cytometry	Prior to conditioning (no specific time indicated)	6% of patients with negative MRD at the time of HCT died of relapse vs. 29% of MRD-positive patients. The 5-year cumulative incidence of relapse after HCT was 40% in patients with high levels of MRD (≥0.1% leukemia cells in ALL and ≥1.0% in AML), 16% among patients with low level of MRD (0.01 to <0.1% leukemia cells in ALL and 0.1 to <1% in AML), and 6% in patients with no MRD
Walter et al. 2011 [91]	99 (AML)	Flow cytometry	Prior to conditioning (no specific time indicated)	2-year estimates of OS were 30.2% and 76.6% for MRD-positive and -negative patients, respectively; 2-year estimates of relapse were 65% and 18%. MRD-positive HCT was associated with increased overall mortality (HR 4.1) and relapse (HR 8.5) relative to MRD-negative HCT
Fang et al. 2012 [92]	424 (AML)	Flow cytometry, cytogenetics	Before and after HCT (~1 month, ~3 months, and ~1 year)	Positive cytogenetics or flow cytometry pre- or post-HCT predicted a significantly worse outcome than negative results. Patients with discordant results had significantly worse outcomes than patients with negative results. The HRs for reduced OS with either positive cytogenetic results or flow results pre-transplantation were 3.1 and 2.5, respectively. The HRs for decreased RFS were 2.7 and 4.1 respectively
Miyazaki et al. 2012 [93]	31 (AML), 10 (ALL)	Flow cytometry and Q-RT-PCR for *WT1* mRNA	Post-HCT on days 28, 56, 100, and 365	The duration of OS was significantly associated with the detection of MRD by flow cytometry ($p = 0.014$), whereas no significant difference of RFS was observed between the MFC-positive and -negative groups ($p = 0.068$)
Zhao et al. 2012 [89]	139 (B and T ALL; Ph+/–)	Flow cytometry and Q-RT-PCR	Different time points after allogeneic HCT	MRD-positive patients had cumulative incidence of relapse of 54% vs. 8% in MRD-negative patients. MRD status after transplantation was an independent prognostic factor for EFS, OS, and relapse ($p < 0.001$, $p = 0.013$, and $p < 0.001$, respectively)

MRD burden. Taken together, however, the data are fairly consistent, showing a very high risk of relapse (~75%) in cases with high levels of MRD prior to HCT, an intermediate risk of relapse in cases with low-level MRD (~50%), and a much smaller risk of relapse in those without MRD (~15%).

MRD detection following transplant is likewise associated with a high risk of subsequent relapse. This is true for Ph^+ ALL and Ph^- ALL cases. In the latter setting, studies have found the relative risk of relapse associated with MRD to be roughly 5–10-fold, with relapse occurring within a few months of MRD detection [94,95]. The situation in Ph^+ ALL is more complicated; PCR must be performed on both the "p210" *BCR-ABL* variant transcript (found in CML and some ALL), and the "p190" *BCR-ABL* transcript (found only rarely in CML but common in ALL). All studies of Ph^+ ALL have demonstrated excess relapses in MRD-positive cases following transplant [96–98]. However, the data suggest that the risk of relapse associated with p190 *BCR-ABL* MRD is stronger than with p210 *BCR-ABL* [98]. For p190 MRD, the relative risk was 8.7, whereas for p210 *BCR-ABL* transcripts it was 2.2. Note that this difference in risk with different *BCR-ABL* transcript variants was also seen in the pre-transplant MRD assessment. The median time from first MRD detection to relapse was 75 days. Spinelli et al. [99] correlated MRD clearance immediately before and 30 and 100 days after HCT with outcome in 43 adult "high-risk" ALL patients by RQ-PCR using one or two molecular probes for *BCR-ABL, MLL/AFF1* or rearrangements of the T-cell receptor or immunoglobulin genes. At 36 months, the OS of the 37 patients who underwent HCT in hematologic remission was 80% for those who were PCR negative before transplantation compared with 49% for PCR-positive patients and the cumulative incidence of relapse was 0% and 46%, respectively. The relapse rate of patients who were PCR negative at day 100 after transplantation was remarkably low (7%) compared with that among patients who were PCR positive (80%).

Achieving a molecular CR *before* HCT is a highly desirable associated subsequent response to the transplant. Zhao et al. studied 139 patients with ALL undergoing allogeneic HCT, and found that those with MRD after transplantation had lower EFS (54%) and a higher cumulative incidence of relapse (54%) compared with an EFS of 80% and a CIR of 8% in MRD-negative patients. Multivariate analysis showed that MRD status after transplantation was an independent prognostic factor. A good correlation was found between the MRD results of flow cytometry and RQ-PCR [89]. Thus, the achievement of a pre-HCT molecular remission is a desirable goal in high-risk ALL, though it is not known if continued, more aggressive, or experimental therapy to treat MRD pre-transplant (1) can change an MRD-positive to MRD-negative status or (2) is associated with an increased toxicity that might actually adversely affect transplant outcome.

Of note is that most MRD studies have used BM samples rather than peripheral blood (PB). In precursor B-cell and Ph^+ ALL, the level of MRD is higher in BM than PB, which makes BM the preferred source for disease monitoring. However, the use of PB to detect MRD has several practical advantages over the use of BM, especially in children, as PB sampling is simple and relatively painless, allowing more frequent monitoring, which may offset the sensitivity advantage of BM [100,101].

MRD detection in acute myeloid leukemia (AML) following chemotherapy

In AML, the use of PCR-based detection of MRD is most commonly used for cases containing unique breakpoint fusion regions, such as t(15;17), t(8;21), and inv(16). In contrast, flow cytometry assays can be used to detect abnormal patterns of lineage and differentiation-specific markers suggestive of leukemia blasts in the majority of AML cases.

Acute promyelocytic leukemia (APL) is characterized by the t(15;17) translocation, which results in the promyelocytic leukemia/retinoic acid receptor-alpha or *PML/RARα* gene juxtaposition. APL patients who have residual disease after induction or consolidation therapy have a significant risk of relapse [102,103]. Serial quantitative MRD monitoring by PCR until completion of maintenance therapy identifies patients at high risk of relapse in APL [104], and the detection of MRD after first consolidation is a powerful predictor of relapse. Patients with an MRD level of 10^{-3} or more had a >10-fold higher relapse rate at 5 years compared with a level of $<10^{-3}$ In APL; there is evidence that the analysis of peripheral blood may be as informative as that of BM [105].

Disruptions of the core binding factor genes, runt-related transcription factor-1 (*RUNX1, AML1*), and core binding factor β subunit (*CBFB*) are involved in the t(8;21) and inv(16)/t(16;16) "favorable" risk translocations, found collectively in 15–20% of adult and pediatric AML cases. However, the mere qualitative detection (yes or no) of the *RUNX1/RUNX1T1* and *CBFB/MYH11* gene transcripts has limited value in monitoring MRD and predicting relapse since these transcripts persist during long-term remission [106–114]. Reciprocal rearrangements of the "mixed lineage leukemia" (MLL) gene on chromosome 11q23 are associated with unfavorable prognosis. The most frequent 11q23/MLL rearrangements detected by RT-PCR are the t(11;19)/*MLL/MLLT1* and the t(9;11)/*MLL/MLLT3* [115]. Intragenic mutations of the *MLL* gene (*MLL-PTD*; partial tandem duplications) have an unfavorable prognostic relevance [116]. *MLL-PTD* positivity detected by RT-PCR or RQ-PCR after standard chemotherapy significantly correlates with leukemia recurrence [117].

Quantification of MRD is essential in these AML variants [14,109]. Several groups have attempted to define the critical level of MRD that accurately segregates good and poor outcome. In general, a post-therapy MRD level of less than 1% as determined by PCR analysis of fusion or mutated genes has been associated with a relatively low risk of relapse [118–123]. MRD investigation at the end of treatment might have the best prognostic value in core binding factor-leukemia [124]. Schnittger et al. created a score for risk stratification of AML by combining the transcription ratios at diagnosis and after 3–4 months during treatment [125].

Immunophenotypic detection of MRD by flow cytometry is useful in AML, although the published experience is less than that in ALL. The clinical significance of positive MRD can vary with the time of assessment during the clinical course, and several studies have identified specific cut-off values of MRD after the induction and consolidation therapy that are associated with outcome [126]. Cut-off levels to distinguish flow cytometry associated with significant survival impact MRD positive from MRD negative vary, ranging from 0.035% to 1%, with most studies using 0.1% as the level of clinically significant MRD [118]. Coustan-Smith et al. [128], using a flow cytometry MRD assay, reported a 2-year OS of approximately 30% in patients with MRD compared with more than 70% in patients without MRD. Sievers et al. [129] found immunophenotypic abnormalities in 16% of 252 children with AML who achieved morphologic CR with initial induction therapy, with MRD highly associated with a poor outcome. Multivariate analysis has shown MRD to be independently associated with relapse and survival [118,130].

The expression of the Wilms tumor gene (*WT1*) is a potential target for MRD detection, as it is overexpressed in approximately

90% of AML cases, and is expressed at low levels in normal cells [131,132]. Several groups have reported that a high *WT1* level at diagnosis is associated with poor prognosis [133]. In some studies, the increase in *WT1* transcripts during therapy was associated with subsequent relapse [131,134] and correlated with other disease markers, such as leukemia-specific fusion transcripts [132]. Polak et al. demonstrated that quantitative monitoring of *WT1* expression in PB of patients with AML before and after HCT is a useful tool for MRD monitoring that correlates with clinical outcome [135].

The most common genetic mutations found in AML involve fms-related tyrosine kinase-3 (*FLT3*) and nucleophosmin (*NPM1*) and occur in approximately 25–35% of cases or more [136]. The most common *FLT3* gene alteration is an internal tandem duplication that causes a 5–100 base-pair addition to the juxtamembrane domain. Primers can be made that allow for leukemia-specific amplification for a specific patient [137–139]. However, the *FLT3* mutation is not very stable, and around 10–20% of the time patients relapse without the *FLT3* mutation [140,141]. Mutation-specific PCR reactions have been constructed for the most common point mutations in *NPM1*, and many potential mutations exist [142], including *CEBPA*, *MLL*, *DNMT3A*, and *IDH1/2,* among others [136]. However, it is unlikely that PCR mutation monitoring will replace the faster and nearly equally sensitive flow cytometry for MRD evaluation.

MRD in AML in the HCT setting

MRD at the time of HCT has a major impact on transplant outcome in AML. Walter et al. [91] reported that pre-HCT MRD is associated with increased risk of relapse and death after myeloablative HCT for AML in first morphologic CR. Among 99 AML patients who underwent myeloablative HCT, 24 had positive MRD pre-HCT as determined by flow cytometry. Two-year estimates of overall survival were 30% and 77% for MRD-positive and MRD-negative patients, respectively; 2-year estimates of relapse were 65% and 18%, respectively. After adjustment for cytogenetic risk, secondary disease, incomplete blood count recovery, and abnormal karyotype pre-HCT, MRD-positive HCT was associated with increased overall mortality (hazard ratio, HR 4.1) and relapse (HR 8.5) relative to MRD-negative HCT. Fang et al. [92] reported that among 424 patients, positive cytogenetic or flow cytometry results at time of transplant, compared with patients who had double-negative test results, had a significant impact on overall survival and relapse-free survival. The HRs with either positive cytogenetic results or positive MFC results pre-transplantation were 3.1 and 2.5, respectively, for reduced overall survival and 2.7 and 4.1, respectively, for decreased recurrence-free survival.

There have been few studies documenting the prevalence and significance of MRD in AML following HCT. This due in part is to the fact that the most common translocations found in AML – for example, t(15;17), t(8;21), and inv(16)/t(16;16) – are associated with reasonable outcomes with conventional chemotherapy, and therefore are underrepresented in the transplant population.

The significance of MRD following transplantation depends largely on the specific genetic subtype of AML, and generally correlates with the "rules" seen in the chemotherapy setting. Thus, in t(15;17) AML, the detection of the *PML/RARα* transcript following HCT is highly correlated with relapse [143,144]. In t(8;21) AML, the detection of *RUNX1/RUNXITI* transcripts remarkably often persists after allogeneic transplant, without subsequent relapse [108–110]. Too few cases of inv(16)/t(16;16) have been studied in the transplant setting to draw a firm conclusion about its association with relapse [107,145].

The tumor suppressor gene *WT1,* which is overexpressed in >90% of patients with AML, has been used as a marker of MRD following HCT, with a number of studies demonstrating correlation between *WT1* expression after transplant and relapse [93,146–148]. Ogawa et al. [147] studied 72 patients (50 AML, 15 ALL, and 7 CML), post HCT, and all 20 patients who relapsed showed elevated *WT1* transcripts at the time of relapse. After relapse, patients were treated with some form of immunomodulation (donor lymphocyte infusions or discontinuation of immunosuppressive therapy). The calculated *WT1* transcript doubling time that occurred with relapse for patients was significantly longer for patients who responded to immunomodulation (a median doubling time of 26 days) compared with non-responders (a median of 6 days). It is unclear, however, if the same information with regard to the kinetics could also be produced by serial flow cytometry studies. *WT1* being investigated as a potential target for immunotherapy and *WT1* transcript levels thus may indicate if particular patients are more susceptible to this therapeutic approach.

MRD in chronic myelogenous leukemia (CML) following tyrosine kinase inhibitor (TKI) therapy

Monitoring the *BCR-ABL* transcript level during therapy with TKIs is essential to evaluate response and guide therapy. Indeed, the guidelines of the European Leukemia Network (ELN) and the National Comprehensive Cancer Network (NCCN) are based on response milestones defined by cytogenetic and molecular response, with the PB PCR for *BCR-ABL* being the primary method of monitoring once a cytogenetic remission is completed. The rate of decline and level of *BCR-ABL* after imatinib therapy predicts the achievement of major molecular response (MMR), achievement and duration of complete cytogenetic response, and progression-free survival [149–152]. In addition, an increase in *BCR-ABL*, particularly the loss of MMR, is associated with a loss of cytogenetic response and the presence of ABL kinase domain mutations [150,153]. More recent studies demonstrated that after 3 months of TKI therapy, the failure to reduce *BCR-ABL* to less than 10% IS (International Scale) are associated with worse outcomes, compared with those patients who have a dramatic reductions to <1% IS, who have a superior outcome [154]. The achievement of an MMR is a "safe haven" associated with rare cases of resistance or progression. ELN and NCCN guidelines recommend PCR *BCR-ABL* testing on PB at 3-monthly intervals, with BM examinations for morphology and cytogenetics, in addition to testing for *ABL* mutations, in cases where the *BCR-ABL* rises significantly (~5–10-fold over two measurements 1 month apart).

MRD detection in CML after transplantation

The clinical utility of MRD detection of the chimeric *BCR-ABL* transcript was first shown in the HCT setting, and a large number of results demonstrate the strong association of MRD and relapse in CML after transplantation. Early studies, prior to the development of quantitative PCR, showed that the mere qualitative detection of *BCR-ABL* was associated with relapse, and that *BCR-ABL* detection was equally informative from PB or BM specimens [94]. The advent of "real-time" quantitative *BCR-ABL* has made the evaluation of disease burden, and thus the risk of relapse, more precise, although the perfection of robust quantitative assays requires a dedication to rigorous laboratory procedures [155,156].

The highest risk of relapse associated with *BCR-ABL* transcript detection appears to be between 3 and 12 months after transplant [157,158,161]. In one study of 346 patients post-transplant, a positive

BCR-ABL transcript assay 6–12 months post-transplant was associated with a 42% risk of relapse compared with a 3% risk of relapse in PCR-negative patients. Tests earlier than 3 months post-HCT were not strongly associated with relapse. MRD can be detected by quantitative PCR for years after HCT. *BCR-ABL* transcripts have been detected in 25–50% of patients 3 or more years post-transplant, with subsequent relapse rates of around 10–20% [160–163]. Occasional patients in CR for longer than 10 years post-HCT have been found to be persistently MRD positive [164].

The type of transplant (allogeneic, T-cell depleted or unrelated) affects the association of MRD and relapse. This is presumably due to the immunologic effect associated with an allograft ["graft-versus-leukemia" (GVL)]. Transplants from unmanipulated unrelated donor grafts had a lower risk of relapse compared with matched related transplants. Patients undergoing T-cell depletion have a very strong association of MRD detection and subsequent relapse [160,165]. Thus, although T-cell depletion decreases graft-versus-host disease, it clearly does so at the cost of the associated GVL effect.

The quantification of *BCR-ABL* transcripts by quantitative PCR further refines the predictive value of MRD detection in CML [163,166–172]. For example, Lin et al. demonstrated that low residual *BCR-ABL* transcript levels after transplant were associated with a very low risk of relapse (1%), compared with a 75% relapse rate in patients with increasing or persistently high *BCR-ABL* transcript levels [173]. Olavarria et al. studied 138 CML patients "early" (3–5 months) after transplant and found that the *BCR-ABL* transcript level was highly correlated with relapse [170]. Patients with undetectable *BCR-ABL* transcripts had a 9% risk of relapse, compared with patients with a "low" (<100 *BCR-ABL* transcripts/μg RNA) or "high" (>100 copies *BCR-ABL*/μg) level of transcripts, who had a cumulative relapse rate of 30% and 74%, respectively. In addition, in a study of 379 CML patients "late" (>18 months) post-HCT [163], 90 (24%) had at least one positive assay and 13 of the 90 (14%) relapsed. Conversely, only three of 289 patients who were persistently *BCR-ABL* transcript negative relapsed (HR of relapse = 19). A rising *BCR-ABL* transcript level was a reliable portent of relapse. The kinetics of *BCR-ABL* can also be used to monitor response in patients receiving donor lymphocyte infusions (DLIs) for relapsed CML [174]. It is common to monitor *BCR*-ABL in PB every three months until 2 years post-transplant, then every 6 months until 5 years and yearly afterwards.

MRD in chronic lymphocytic leukemia (CLL)

In CLL, MRD can be measured by studying IgH V-D-J rearrangements or by flow cytometry. An international standardized approach for flow cytometric four-color analysis has been developed that is applicable to all CLL sample types and treatment regimens [175,176]. In head-to-head comparisons of RQ-IgH-PCR and flow cytometry, PCR has been found to be slightly more sensitive, with approximately 20% of flow cytometry-negative cases being found to be PCR positive for clonal rearrangements. However, there was a close correlation and 95% concordance with RQ-PCR for detection of CLL above 0.01% [175]. The increased sensitivity of PCR must be weighed against the relative ease and speed of flow cytometry compared with the more complicated and costly PCR technique.

Allogeneic HCT plays a role in the treatment of CLL (see Chapter 60), especially in patients with high-risk CLL prognostic factors of unmutated IgV_H, del(11q), and del(17p) [177–180]. In CLL cases treated with either anti-CD52 antibody-based therapy (alemtuzumab) or autologous transplant, the presence of MRD (by either flow cytometry or PCR) is very strongly associated with subsequent relapse [181,182]. By contrast, MRD negativity following allogeneic transplantation is associated with a very low relapse risk, although some patients remain with low-level MRD but do not overtly relapse. Slow clearance of MRD after HCT has been seen in a number of studies where some patients became MRD negative several months after transplant [182,183]. Moreno et al. analyzed MRD by quantitative PCR and flow cytometry in 40 patients with CLL who underwent HCT. Fifteen of 25 patients receiving autografts suffered a relapse, with increasing levels of MRD being observed before relapse in all of them. In contrast, in allografted patients, MRD did not correlate with outcome [184]. Itala et al. evaluated MRD after allogeneic HCT in 11 patients with poor-risk CLL by flow cytometry or allele-specific oligonucleotide-PCR (ASO-PCR). Flow cytometry did not detect MRD in any of the samples that were PCR negative. In contrast, ASO-PCR detected MRD in samples that were negative for MRD by flow cytometry in 22% of the analyses. All patients treated with allogeneic transplantation achieved or maintained hematologic CR, and five patients became PCR negative. None of the patients who became PCR negative after allogeneic transplantation has relapsed whereas all who remained PCR positive have relapsed [185]. In the setting of reduced intensity conditioning and allogeneic stem-cell transplantation, three patterns of MRD were observed: negative (31%), mixed (24%), and always positive (45%). The cumulative incidence of relapse according to the MRD status at 6 and 12 months after transplantation was significantly different between MRD-negative and -positive patients. Two-year DFS was 93% and 46% for MRD-negative and -positive patients, respectively, at 6 months after transplantation. Similarly, 2-year DFS was 100% and 57% for MRD-negative and -positive patients, respectively, at 12 months [186]. These studies demonstrate that in CLL, MRD negativity following allogeneic transplantation is strongly associated with a very low relapse risk; however, MRD positivity does not always evolve to overt relapse, and may remain low-level MRD positive with no progression to overt relapse, potentially due to graft-versus-tumor activity.

MRD testing in multiple myelomaMM

According to the International Myeloma Working Group (IMWG), complete remission in MM is defined as negative immunofixation of serum and urine, disappearance of any soft tissue plasmacytoma, and less than 5% plasma cells in BM [187]. Stringent complete response is defined as CR plus normal free light chain ratio and absence of clonal plasma cells by immunohistochemistry or two- to four-color flow cytometry, and molecular CR is defined as CR plus negative allele-specific oligonucleotide PCR with a sensitivity of 10^{-5} [187]. Despite the high rates of response following induction therapy and consolidation with autologous or allogeneic HCT, the majority of patients eventually relapse. The high rates of relapse among MM patients who initially respond to therapy suggest that MRD remains after therapy and proliferation of the remaining MM cells ultimately leads to clinical relapse [188]. With the most significant advances in the treatment of MM, including the use of autologous and allogeneic HCT in combination with the immunomodulatory drugs thalidomide and lenalidomide, and also the proteasome inhibitor bortezomib, albeit none curative, the major challenge will be to incorporate genetic and other MRD prognostic parameters into clinical trials that are designed to determine the best way, time, and sequence of administering these therapies.

Genomic aberrations evaluated by interphase FISH have been shown to play a major role in the prognosis and evolution of patients with myeloma. For example, three independent groups [3,189,190] reported that MM patients with t(4;14) or del(17p) fared worst when compared with the other genetic subgroups, especially when associated with high β_2-microglobulin levels or more than 60% plasma cells in the marrow. The poor prognosis associated with −13/del(13q) was further attributed to the fact that t(4;14) and del(17p) patients showed the chromosome 13 aberrations simultaneously, with few patients benefiting from thalidomide maintenance therapy. However, some studies suggest that bortezomib may overcome the poor prognosis conferred by chromosome 13 deletions at relapse in MM patients with high serum albumin [191,192]. Taken together, these data have broad implications for patient counseling, choice of therapy, and innovative molecular approaches to clinical investigations for both younger and older MM patients [193].

Studies have suggested that allogeneic HCT for MM results in CR rates of 22–67%, with molecular remissions in about one-third [194,195] and prolonged DFS in 25–33% of patients [196,197] (see Chapter 56). Martinelli et al. [195] noted that MM patients who achieved a molecular CR after allogeneic or autologous HCT had a significantly lower relapse rate (41% versus 16%) and a longer RFS (35 versus 110 months). Using a sensitive flow cytometry assay, Rawstron et al. [198] quantitated normal and neoplastic plasma cells and compared their results with standard immunofixation in 45 patients undergoing high-dose chemotherapy. By flow, neoplastic plasma cells were detected in 42% of the patients at 3 months after transplantation (compared with 27% by immunofixation). Patients with detectable MRD showed a significantly shorter progression-free survival (median 20 months) compared with those with no detectable disease (median >35 months), and a significantly higher risk of early disease progression. Sarasquete et al. [199] compared the clinical utility of MRD in MM by allelic-specific oligonucleotide RQ-PCR and flow cytometry. Owing to technical issues, allelic-specific oligonucleotide RQ-PCR was evaluable in only 75% of patients compared with 90% for flow cytometry; however, PCR detected residual myelomatous cells (median 0.014%, range 0.001–0.11%) in 17 patients compared with 11 patients by flow cytometry. This head-to-head comparison showed that the ability to predict outcome in MM is similar in PCR and flow cytometry (~0.01% level), with flow cytometry having the critical advantage of speed, possibly allowing for real-time clinical decisions, including dose escalation and de-escalation strategies or the timing of stem-cell harvests based on MRD detected during therapy.

Maintenance therapy, defined as extended drug therapy administered after achieving a remission or plateau phase with MRD, may be beneficial. Typically, maintenance therapy involves the use of a lower dose of an anti-myeloma agent and aims to provide sustained control of MRD while being well tolerated and easy to administer [200]. Although maintenance therapy is unlikely to achieve complete eradication of the malignant clone, it may provide sustained control of MRD and delay both relapse and the need for more intensive therapy. Ultimately, clonal selection will likely produce a resistant population that causes relapse; however, a meaningful alteration in disease course and delay in relapse are clinically beneficial [201].

Not all patients with detectable MRD progress to relapse

This phenomenon has sometimes been referred to as "dormancy," although it is not clear that the leukemia (if it is leukemia) is truly inactive. There are three clear demonstrations of dormancy. The first is in t(8;21) AML following conventional chemotherapy, and also in CML following HCT [14,202]. In t(8;21) AML, the *RUNX1/RUNX1T1* (*AML1-ETO*) messenger RNA can be detected in a minority of lymphoid and erythroid colonies taken from remission samples and long term survivors after HCT, suggesting that the disease involves a primitive leukemia progenitor cell [203,204]. As such, some MRD in this disease may arise from non-leukemia lymphoid cells. Furthermore, another example of dormancy is the observation that late relapses in pediatric ALL (>10 years after CR) have the same clonal IGH V-D-J gene rearrangement as at diagnosis [205].

How can such examples of dormancy be explained? Perhaps prolonged immune surveillance, most relevant after HCT, can control the expansion of a leukemia clone. Or, as in the example of t(8;21) noted above, the MRD assay may detect signal in a cell lineage not involved in the leukemia. Lastly, a residual leukemia cell may be "pre-leukemia," not having all the mutations necessary for malignancy, or "post-leukemia," whereby additional mutations have rendered the clone relatively inert. Regardless, it is likely that the clinical definition of "cure" does not mean the elimination of all cells involved in the leukemia process. Further studies of dormancy may clarify what it takes to "cure" leukemia.

Conclusion – the future of MRD

The detection of MRD is strongly associated with relapse in almost all clinical situations. Where do we go from here?

First, MRD will be used more extensively to guide treatment options. For example, patients with "favorable" risk acute leukemia will be "restaged" by their MRD status during therapy, with treatment adjusted as necessary (for example, moving a patient with CR by morphology but MRD positive to transplant). Patients with MRD after transplant will have their immunosuppression adjusted, or placed on trials using immunotherapy or drugs to slow or abort relapse.

Second, MRD will be used as a surrogate for outcomes. If the presence of MRD at 1 year is highly correlated with relapse and survival, why not have MRD be the early end-point of clinical trials, rather than the traditional 5–10-year survival outcome end-point? In recent phase III trials in CML, the MRD end-point of MMR at 12 months was used as the primary or secondary study end-point [206–208]. The acceptance of MRD as a trial end-point surrogate would greatly reduce study time and costs.

Third, MRD is another example of where technology shapes the questions that can be asked (and hopefully answered). Next-generation sequencing is allowing the study of the complexity of clonal structure in leukemia. It is clear that many (most?; all?) leukemia has many independent clones, which compete against each other before and during therapy, so that treatment, response, and relapse are a large exercise in Darwinian selection [209,210]. Hence, in the future, a combination of MRD detection, cell isolation, and genotyping will likely be used not only to identify the burden of MRD, but also understand which leukemia population has survived, so better to tailor therapy to eliminate the persistent clones.

CHAPTER 26

Pathology of Hematopoietic Cell Transplantation

Keith R. Loeb, Cecilia C. Yeung and Howard M. Shulman
Fred Hutchinson Cancer Research Center and University of Washington School of Medicine, Seattle, WA, USA

Introduction

The hematopoietic cell transplantation (HCT) setting presents pathologists with four major types of complications: toxicities resulting from pre-transplant cytoreductive conditioning regimens, immunological problems [rejection or graft-versus-host disease (GVHD)], infections, and malignancy. Since the previous editions of this book, new biologic insights on the role of the endothelium as well as advances in diagnostic and treatment modalities have affected some of the attitudes regarding the role and application of surgical pathology in the HCT setting [1–3]. There has been a steady increase in matched, unrelated hematopoietic cell donors (using peripheral and cord blood), prolonged prophylaxis for GVHD beyond day 100, and reduced-intensity conditioning regiments with older recipients and patients with significant pre-transplant comorbidities. Quality of life indices [2] and combinations of serologic biomarkers [3,4], clinical parameters such as weight gain, and bilirubin [5,6] have been validated for predicting survival outcomes with GVHD. The frequency of severe liver complications [sinusoidal obstructive syndrome (SOS) and hepatic GVHD] has markedly declined as a result of changes in the pre-transplant conditioning regimen (see Chapters 20, 21, and 94) [7]. Severe viral infections have declined with earlier detection by sensitive molecular methods and from the widespread use of effective antiviral agents**.** The use of open lung biopsies for suspected infection has declined with the increasing use of bronchoalveolar lavage (BAL), newer CT imaging studies, and serologic and multiplex PCR tests for presumptive fungal or viral infections, respectively. The bronchiolitis obliterans syndrome of chronic GVHD now includes small airway lesions of lymphocytic bronchiolitis and constrictive bronchiolitis [1].

Pre-transplant evaluation

Hematopoietic system

Before a patient is accepted for HCT, the referral evaluation is used to confirm the diagnosis, review eligibility for available protocols, and identify potential complications that may influence transplant decisions. The pathologist reviewing material from the referring institution will need relevant flow cytometry, immunohistology, molecular, and cytogenetic data and also details of recent therapy. Data from the original malignancy are essential for planning therapy, subsequent disease monitoring, and minimal residual disease detection. The patient is often in complete remission at the time they arrive at the tertiary referral transplantation center and the essential molecular, immunophenotypic, and cytogenetic characteristics of the malignancy can no longer be determined. It is therefore very important to characterize the tumor fully at presentation to facilitate subsequent therapeutic planning and disease monitoring. The pathology report from the referring institution should provide a detailed description of all ancillary testing results.

Prior to undergoing HCT for hematologic malignancies, the marrow is evaluated to determine remission/relapse status. Patients who are transplanted in complete remission without any detectable minimal residual disease (MRD) have a much better prognosis. The pre-transplant detection of MRD by multiparameter flow cytometry, cytogenetics, or molecular tests is a strong independent negative prognostic indicator but does not exclude possible cure [8]. Chapter 25 provides an extensive review of the various modalities used to monitor and detect minimal residual disease. Although polymerase chain reaction (PCR)-based molecular testing is an extremely sensitive means of detecting minimal residual disease, it depends on the presence of a unique molecular signature (mutations or translocations) that can be targeted by PCR. Multiparameter flow cytometry, on the other hand, provides a very sensitive means of MRD detection. It can be easily applied to most hematologic malignancies and has the ability to detect as few as 0.01% malignant cells without a prior immunophenotype signature for comparison [9–11]. In our practice, we use clinical multiparameter flow cytometry incorporating panels with up to 10 antibodies that can be used to define cell lineage, detect abnormal immunophenotypes, and monitor maturation of hematopoietic cells [12]. The identification of malignancy is based on the fact that normal hematopoietic maturation demonstrates a characteristic and reproducible pattern of cell surface antigen expression that is altered in most hematopoietic tumors. Common tumor-specific antigen variation includes (1) the expression of unique antigens not usually associated with a given lineage, (2) the increased or decreased expression of certain antigens during maturation, (3) an abnormal immunophenotype maturation pattern, and (4) a homogeneous immunophenotypic population suggesting a block in maturation [11]. Although prior immunophenotype will aid the detection of MRD, many malignancies undergo immunophenotypic evolution. The immunophenotype of a given leukemia can change during the course of therapy, possibly due to selection of resistant clones. Clinical flow cytometry is a rapidly evolving field and there is enormous variability in methodology that impacts tumor diagnosis and MRD detection. For example, many laboratories report levels of blasts based on the number of CD34-positive cells within the “blast gate” without indication of whether the expanded immature population is abnormal or the result of a reactive process in a regenerating marrow. There is a developing international effort to standardize the practice of clinical flow cytometry in diagnosing and classifying leukemias and lymphomas [13].

Compared with multiparameter flow cytometry, MRD detection by PCR analysis has enhanced sensitivity but requires a unique molecular target (mutations, translocations, or gene rearrangements) for detection. For this reason, it is important to determine potential molecular abnormalities at diagnosis for subsequent therapy and disease monitoring. The diagnosis of many B- and T-cell lymphomas involves PCR studies to determine clonality, targeting gene rearrangement or detecting potential translocations, including *t*(14,18) in follicular lymphoma or *t*(11,14) in mantle cell lymphoma that can then be used to monitor recurrent post-transplant disease. In the case of lymphocytic leukemia, the rearranged genes serve as ideal targets for molecular detection. However, it is difficult and expensive to design unique tumor-specific PCR primers and molecular evolution of the tumor may interfere with PCR-mediated detection. Wu et al. used high-throughput sequencing of the T-cell receptor to diagnose minimal residual T-cell acute lymphoblastic leukemia/lymphoma [14]. They sequenced the variable regions of T-cell antigen receptor genes amplified using multiplex PCR that targeted all potential V–J rearrangement combinations. They identified the expanded neoplastic clone in the diagnostic sample and subsequent post-therapy sample with MRD. In a subset of cases, high-throughput sequencing detected MRD that was not identified by the concurrent clinical multiparameter flow cytometry. Additional studies have reported a similar assay for monitoring B-cell neoplasms [15,16]. These studies demonstrate the enormous power that high-throughput DNA sequencing will have on the detection and monitoring of lymphocytic neoplasms. In contrast, myeloid neoplasms lack gene rearrangements, hence molecular detection of clonality is more problematic. The molecular detection of myeloid neoplasms is dependent on tumor-specific mutations and translocations including Bcr/Abl in CML, Jak2 (V617F) in myeloproliferative neoplasms [17], and NPM1, Flt3, CEBPA mutations, or other cytogenetic abnormalities in acute myeloid leukemias [18]. Many of these tumor-specific mutations represent therapeutic targets and sensitive molecular studies are being designed for the early detection of resistant mutations that can guide therapeutic decisions [19].

Proper disease classification is essential to direct pre-transplant conditioning, determine prognosis, and provide markers for disease monitoring. Many patients being considered for HCT have a long history of previous therapy and biopsies. Ideally, the original diagnostic sample and a recent biopsy should be reviewed since a single biopsy may not be sufficient to confirm both disease classification and recent disease activity. Prior and recent drug therapy can alter the morphology and immunophenotype of the neoplastic cells, making it difficult to evaluate a biopsy from a recently treated patient. Granulocyte colony-stimulating factor (G-CSF) and other cytokines may cause confusing left shifts in hematopoietic cells and abnormal monocytic hyperplasia [20]. Bisphosphonates given for multiple myeloma may thicken trabecular bone in pre-transplant marrow biopsies. Demethylating agents can induce cellular maturation and mask morphologic and immunophenotypic dysplasia [21].

In general, disease classification is made on the original diagnostic sample and recent disease activity is determined from subsequent biopsies. Disease subclassification of myelodysplastic syndromes by World Health Organization criteria relies predominantly on the marrow blast count. Post-transplant survival for both de novo and secondary myelodysplastic syndrome/transformed acute myeloid leukemia is related to the disease stage (blast count), cytogenetics, conditioning regimen, and donor relationship [22]. Myeloproliferative neoplasms tend to evolve over time with an increasing myeloid blast population. The timing of HCT is very important since many studies have shown that patients transplanted in chronic phase have a much better prognosis than those in the accelerated phase or blast crisis. While most patients with chronic myeloid leukemia can achieve complete clinical, cytogenetic, or molecular remission with targeted tyrosine kinase inhibitors, the disease often evolves with emergence of resistant mutations (clones). The determination of current disease activity is essential for planning when to proceed with a stem-cell transplant.

A detailed evaluation of myelofibrosis may be needed to distinguish chronic myeloproliferative disorders including essential thrombocythemia, primary myelofibrosis, and polycythemia from acute panmyelosis, myelodysplastic syndromes, and metastatic disease. In many cases, the marrow is inaspiratable, hindering the morphologic evaluation of potential dysplasia or elevated myeloid blast population. Preparation of touch preparations in the setting of myelofibrosis is essential for cytologic morphology since the marrow is frequently inaspirable. Subsequent immunohistochemical studies for the immature myeloid markers CD34 and CD117, and also potential metastatic carcinoma (cytokeratin), should be considered. When analyzing a severely fibrotic marrow, we find it helpful to perform flow cytometry on cells extracted from a minced bone marrow biopsy rather than a hemodilute bone marrow aspirate. Additional molecular testing for Bcr/Abl and Jak2 (V617F), cytogenetic studies, and a previous clinical history are important to determine the correct diagnosis. Severe myelofibrosis portends slower engraftment but is not a contraindication to HCT [23]. Magnetic resonance imaging of the pelvis and femur can be helpful to assess the extent and distribution of myelofibrosis and other disease [24]. The differential diagnosis of a markedly hypocellular marrow includes aplastic anemia, hypocellular myelodysplastic syndrome, or a reactive process including toxin exposure, drug reaction, or nutritional deficiency. Differentiation between aplastic anemia and hypocellular myelodysplastic syndrome (MDS) requires good morphologic, cytogenetic, and immunophenotypic studies that are often unavailable because of a hypocellular or inaspiratable marrow.

Toxicity from cytoreductive therapy

The cytoreductive therapy given for treatment of underlying malignancy, marrow ablation, and immune suppression may cause widespread multiorgan dysfunction and atypical changes. The frequency, the organ systems involved, and the time of onset are related to both the type and overall intensity of the conditioning protocol. The histopathology within some affected organs, such as the heart, may be disease "non-specific" (edema, hemorrhage, necrosis of myocytes, and interstitial fibrosis), yet the associated clinicopathologic entity may be highly characteristic of toxicity. Other changes due to toxicity, particularly those in the mucous membranes [25], skin, gastrointestinal (GI) tract and lung, cause diagnostic difficulties because of their clinical or histological overlap with GVHD and infection (Figures 26.1–26.4). Studies of these organs with serial biopsies demonstrate the diffuse distribution of conditioning injury and amelioration of these changes with time (Figure 26.5).

Pre-transplant hepatic disease

Pre-transplant liver dysfunction can have a major impact on outcome along with a substantial influence on the choice of conditioning regimen and donor [26]. Liver biopsies carried out to assess the severity and cause of abnormal liver function can identify processes that would jeopardize post-transplant survival and predispose to liver failure, fatal SOS, or fatal infection. Patients at increased risk of developing SOS include those with inflammatory liver diseases demonstrating sinusoidal fibrosis, significant necroinflammatory activity, or bridging fibrosis. Specific diseases include steatohepatitis (Figure 26.6), sinusoidal fibrosis associated with extramedullary

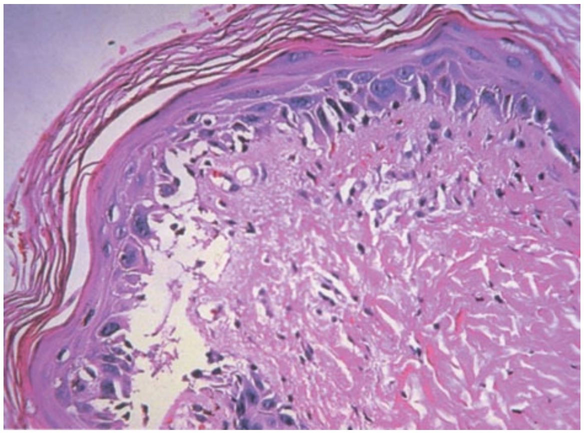

Figure 26.1 Skin biopsy from a recipient of identical twin marrow who had received a single 15mg/kg dose of dimethylbusulfan 15 days previously. The epidermal separation, keratinocyte atypia, and scanty lymphoid dermal infiltrate can also be seen in GVHD. (For a color version of this figure, please see the color plate section.)

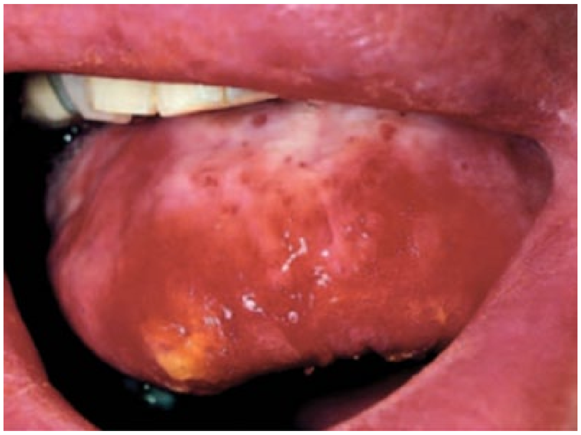

Figure 26.2 Acute glossitis 1 day post-HCT after a conditioning regime of 60mg/kg of cyclophosphamide (CY) followed by 12Gy of fractionated total body irradiation (TBI). There is early mucosal damage with severe erythema and focal atrophy. (For a color version of this figure, please see the color plate section.)

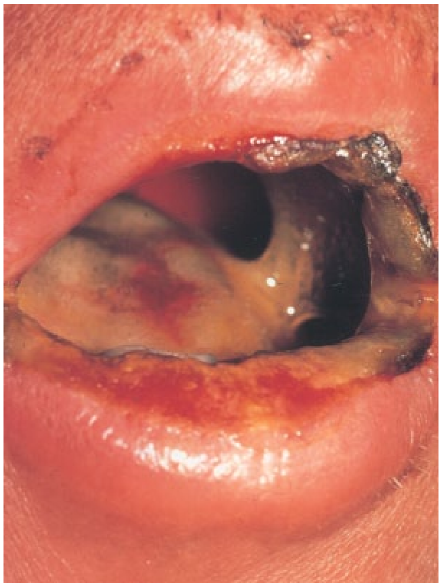

Figure 26.3 Severe mucositis of lips and tongue with pseudomembranous exudate 20 days after HCT following conditioning with TBI and chemotherapy. Similar changes may be present with severe acute GVHD or herpetic infection. (For a color version of this figure, please see the color plate section.)

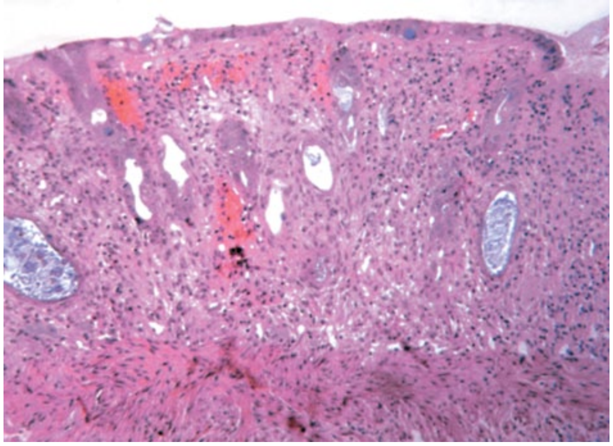

Figure 26.4 Effect of cytoreductive therapy on colonic mucosa, day 7. This biopsy specimen was taken following therapy with busulfan (BU), CY, and TBI (12Gy). There has been obliteration of almost all epithelial cells, leaving cystic crypt remnants. (H&E with Alcian Blue counterstain.) (For a color version of this figure, please see the color plate section.)

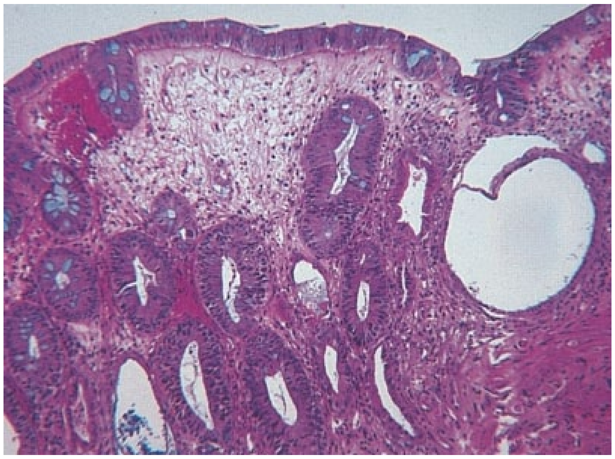

Figure 26.5 Recovery from the effects of cytoreduction therapy on colonic mucose, day 16. This repeat biopsy from the same patient as in Figure 26.4 indicates that regeneration is occurring, although some cystic crypts remain. (H&E with Alcian Blue counterstain.) (For a color version of this figure, please see the color plate section.)

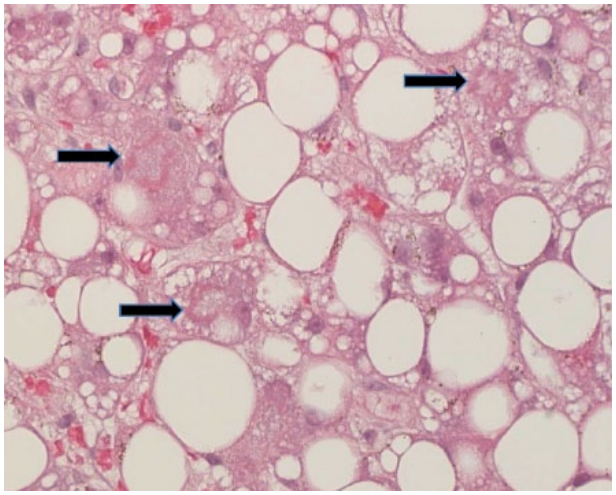

Figure 26.6 H&E-stained liver biopsy demonstrating changes of non-alcoholic steatohepatitis (NASH) with extensive macro- and lesser amounts of microsteatosis, hepatocyte ballooning, and focal Mallory body formation (arrow). (For a color version of this figure, please see the color plate section.)

hematopoiesis from myeloproliferative neoplasia (Figure 26.7), prior toxicity from gemtuzumab ozogamicin (Mylotarg™) (Figure 26.8) and rarely Gleevec® [27], active chronic viral hepatitis, and amyloidosis (Figure 26.9). Poorly compensated cirrhosis is a contraindication for HCT because of the prohibitive risk of developing SOS after myeloablative conditioning regimens. Even compensated cirrhosis has a high likelihood of hepatic decompensation after non-myeloablative regimens [28].

Hepatic sinusoidal obstructive syndrome (veno-occlusive disease)

The most frequent life-threatening regimen-related toxicity involves SOS, a clinical syndrome of jaundice, weight gain, ascites, and painful hepatomegaly that typically develops in the first few weeks after HCT. Initially, this syndrome was called hepatic veno-occlusive disease (VOD), referring specifically to the obliterative lesions within the lumina of small hepatic venules [26,29] (Figure 26.10). However, based on more recent experimental and molecular studies, the authors renamed it sinusoidal obstructive syndrome (SOS), because the primary site of injury occurs in the sinusoids before clinical signs appear. The term SOS reflects the proximate cause, which is toxic injury to zone 3 sinusoidal and venular endothelium related to specific drug metabolites and the intracellular depletion of glutathione stores. Secondary events include a decrease in nitric oxide associated with vasoconstriction and deposition of coagulants evinced by factor VIII staining within the widened venular subendothelial zone, and the perivenular zone corresponding to the pores that drain the sinusoids into the small venules (Figure 26.11). This sequence of events leads to subsequent deposition of extracellular matrix and collagens by activated and proliferated hepatic stellate cells (HSCs) (Figure 26.12). In a study of severe hepatocellular injury before day 100 [defined as alanine aminotransferase (ALT) >30 times the normal upper limit] conducted on 6225 consecutive patients, SOS was

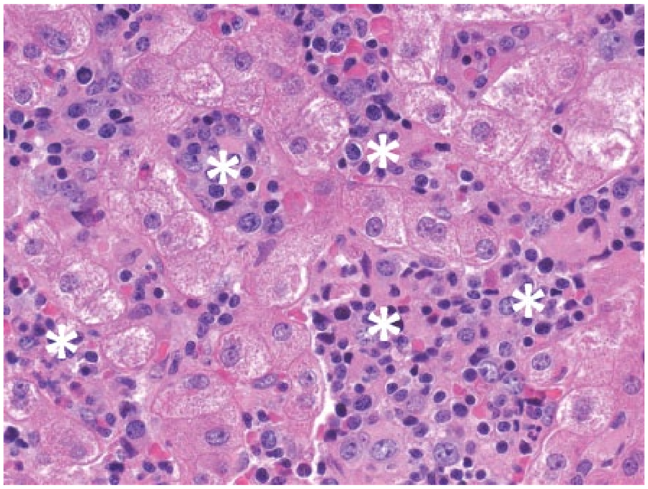

Figure 26.7 H&E-stained section of a pre-transplant liver biopsy from a patient with myelofibrosis. The hepatic sinusoids (white asterisk) are expanded by a mixed cellular infiltrate of hematopoietic precursors. (For a color version of this figure, please see the color plate section.)

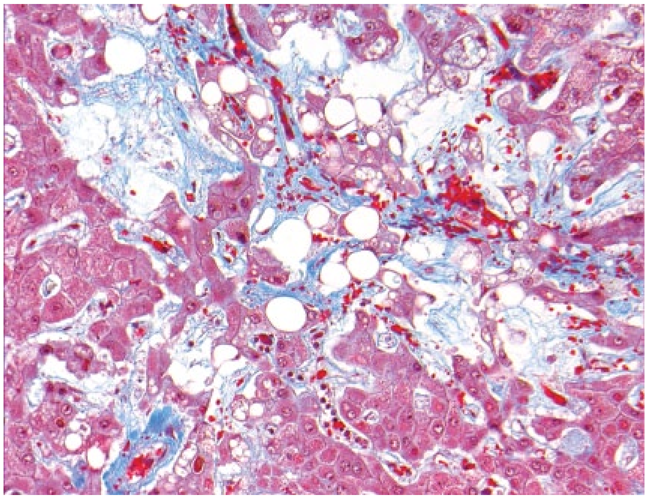

Figure 26.8 Fatal gemtuzamab ozogamicin (Mylotarg™)-associated sinusoidal obstruction syndrome. The obliterated central venule is surrounded by focal sinusoidal fibrosis. (Trichrome stain.) (For a color version of this figure, please see the color plate section.)

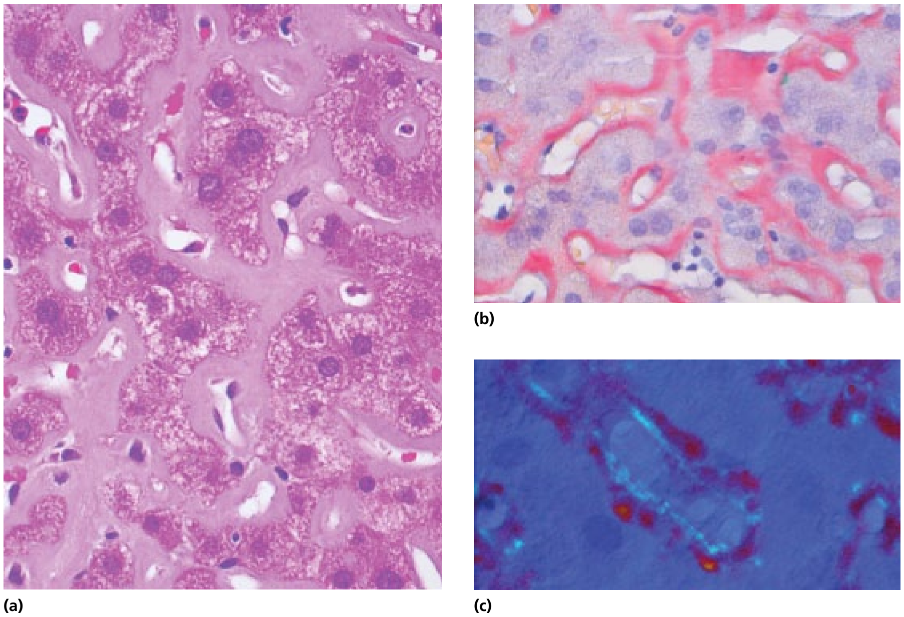

Figure 26.9 (a) H&E-stained section of a pre-transplant liver biopsy demonstrating extensive amyloid deposition in the liver sinusoids. (b) Congo Red stain of the same liver biopsy, with the sinusoidal amyloid deposit highlighted by salmon-pink staining. (c) Congo Red stain under polarized light: the sinusoidal amyloid deposit shows apple-green birefringence. (For a color version of this figure, please see the color plate section.)

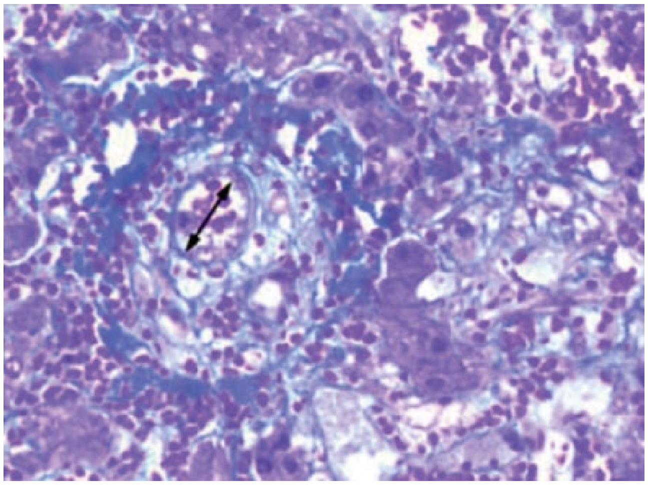

Figure 26.10 Hepatic sinusoidal obstructive syndrome (SOS) 95 days post-HCT for malignancy. The trichrome stain shows the blue outline of a hepatic venule with marked luminal narrowing (arrow shows lumen diameter) caused by subendothelial trapping of red cells. The hepatocytes of acinar zone 3 are severely disrupted. When the clinical diagnosis of hepatic SOS is uncertain, it may be confirmed by a transvenous liver biopsy with measurement of an elevated gradient between wedged and free hepatic venous pressures. (For a color version of this figure, please see the color plate section.)

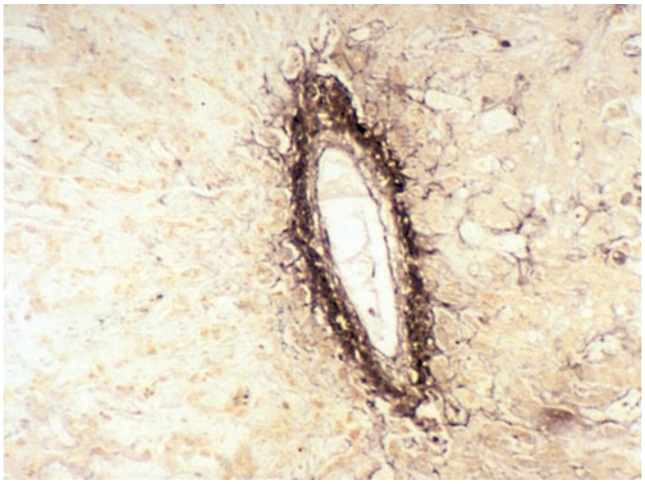

Figure 26.11 Early hepatic SOS showing perivenular staining for procoagulants. Immunohistochemical staining for factor VIII (von Willebrand) demonstrates post-sinusoidal obstruction corresponding to the endothelium-lined pores through which the sinusoids drain into the venules. Immunostaining for fibrin localizes in the same regions. These observations provide some of the rationale for using anticoagulation and anti-thrombotic therapy for hepatic SOS. (For a color version of this figure, please see the color plate section.)

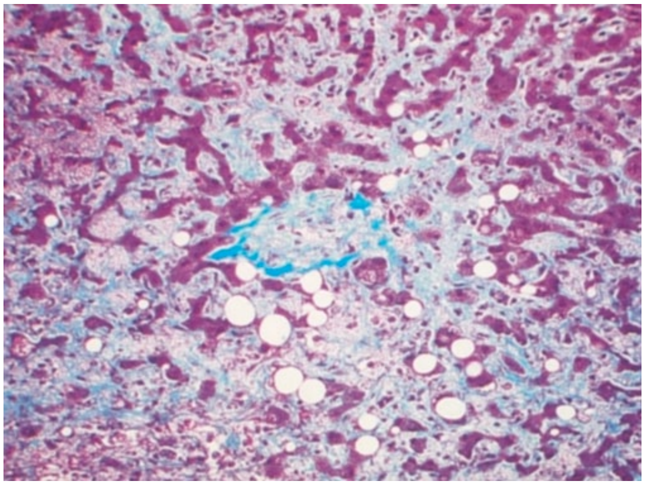

Figure 26.12 Late hepatic SOS, day 63. The trichrome stain demonstrates fibrotic obliteration of the venous lumen with extensive fibrosis in surrounding sinusoids. The resulting vascular obstruction produced intractable ascites. Immunohistochemical stains at this stage reveal extensive deposition of collagen, while fibrin and other blood procoagulants are no longer identifiable. (For a color version of this figure, please see the color plate section.)

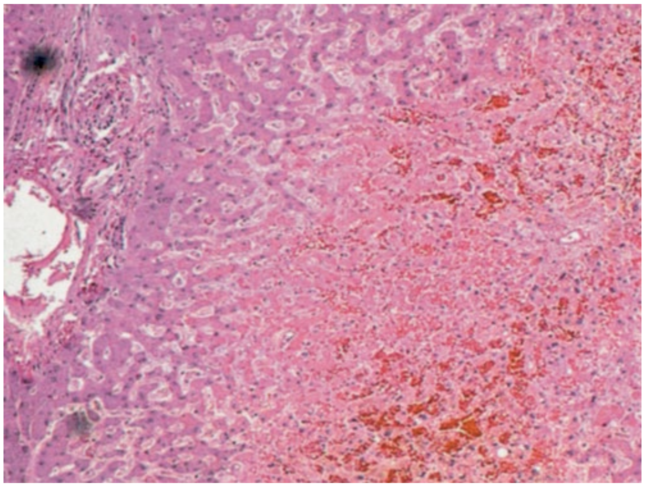

Figure 26.13 Fatal hepatic SOS at autopsy 12 days post BMT for leukemia. At this low magnification, the H&E-stained section demonstrates striking congestion, hemorrhage, and hepatocyte disruption in zone 3 (centrilobular) of the liver acinus toward the right. The portal space and surrounding acinar zone 1 on the left are well preserved. These early severe hepatic SOS lesions at times can be identified with the H&E stain after tissue fixation with B5 or methyl Carnoy's fixative. However, stains for connective tissue are more effective. (For a color version of this figure, please see the color plate section.)

the leading cause of severe hepatocellular injury in 48/88 patients with high ALT, followed by ischemic hepatopathy 32/88 [30]. The frequency of high ALT elevations declined markedly from 1.75% between 1993 and 1995 to 1.06% between 2005 and 2007, reflecting a marked reduction in the prevalence of SOS.

Autopsy specimens reveal that the histology of injury to sinusoids, hepatocytes and venules, best seen with a trichrome stain, may be rapidly progressive. In difficult cases, liver histology using transvenous liver biopsy should be done in conjunction with measurement of the wedged hepatic venous pressure gradient [31]. Examination of serial sections may be needed to identify characteristic histologic changes that may not be present in all levels. The initial injury is to the sinusoidal endothelial cells (SECs), resulting in death of cells which may then detach and embolize, leading to sinusoidal obstruction along with deposition of fibrin and procoagulants in the pores that drain into the venules, and hemorrhage in zone 3 and the space of Disse (Figures 26.10, 26.11, and 26.13). Immunostaining with CD31 demonstrates a loss of endothelium in the perivenular sinusoids and the central venule (Figure 26.14). Frank necrosis of perivenular hepatocytes, demonstrated by their absence of cytoplasmic cytokeratin immunostaining, is often more widespread and severe than the extent of venular injury. A consequence of the sinusoidal obstruction, elevated sinusoidal pressure, ischemia, and fragmentation of hepatocyte cords is the dislodgement of clusters of liver cells, including hepatocytes, which may flow retrograde into portal veins or embolize through disrupted pores into the damaged central venules (Figure 26.15). Within 3 weeks of myeloablative conditioning, the deposition of sinusoidal reticulin is accompanied by a marked linear sinusoidal pattern of α smooth muscle actin staining for HSCs and by an increase in monocytes/Kupffer cells at the interface of ischemic hepatocyte necrosis (Figure 26.16) [26,29]. Later changes include collagenous obliteration of the venules, thickening of the outer wall of the hepatic venules (phlebosclerosis) (Figure 26.17), extinction of zone 3 hepatocytes, and fibrotic replacement of the sinusoids adjacent to the terminal hepatic venules (zone 3) of the liver acinus (Figure 26.12). In prolonged and fatal SOS, the liver may take on a pattern of reversed cirrhosis with fibrotic linkage between destroyed perivenular zones.

Several additional pericentral vein (zone 3) lesions that follow cytoreductive therapy are associated with SOS. Two studies have demonstrated that zone 3 sinusoidal fibrosis and phlebosclerosis, a non-occlusive perivenular fibrosis, are also associated with the same clinical features as SOS [26]. An example of the histologic spectrum is a rapidly developing syndrome of SOS that occurs among some

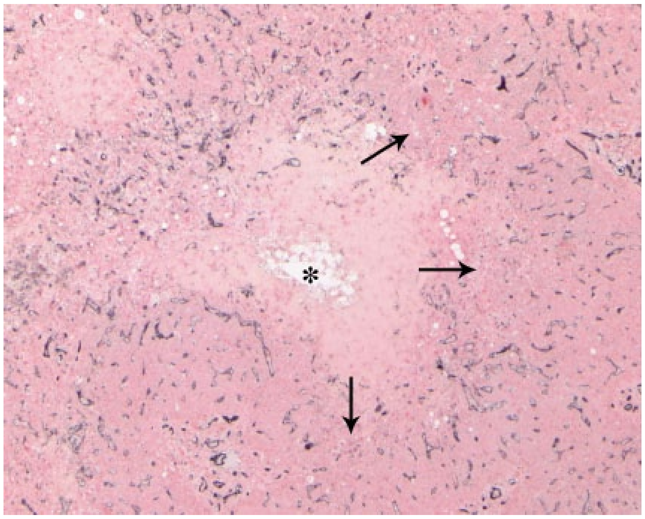

Figure 26.14 CD 31 immunostain of liver with fatal SOS. There has been partial to complete loss of sinusoidal endothelial staining of the hepatic cords in zone 3 (arrows) which surround the subtotally occluded venule lacking an endothelium (asterisk). (For a color version of this figure, please see the color plate section.)

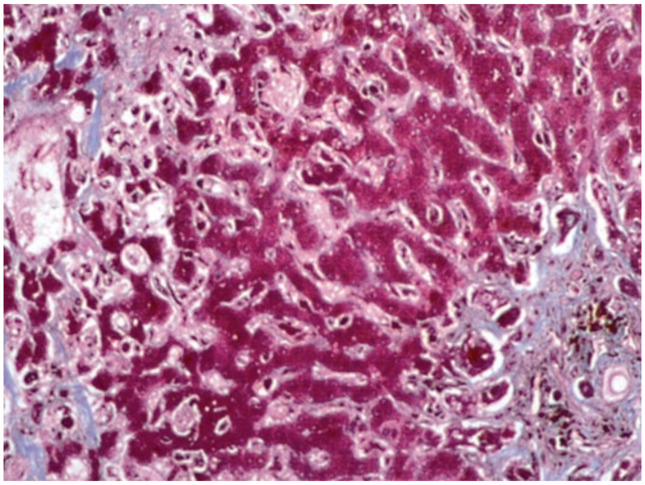

Figure 26.15 Hepatic SOS and coexisting GVHD, day 26. On this trichrome stain, the two most common liver problems after HCT can be differentiated by the zone of the liver acinus that they affect. The expanded portal space in the lower right demonstrates changes from GVHD, including fibrosis, proliferation of atypical cholangioles along the limiting plate, and destruction of small interlobular bile ducts. The SOS lesion along the left margin shows striking collections of embolized hepatocytes beneath the endothelial basement membrane. (For a color version of this figure, please see the color plate section.)

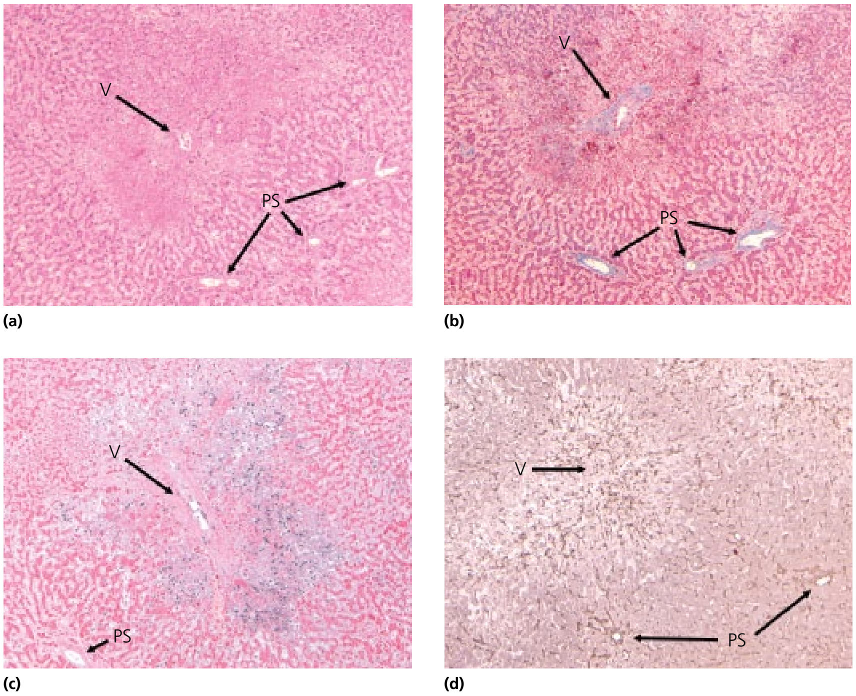

Figure 26.16 Fatal SOS. (a) H&E stain demonstrates a large perivenular zone of hemorrhagic necrosis with destruction of hepatocyte cords surrounding the damaged venule (V); the areas around the portal spaces (PS) are spared. (b) Trichrome stain demonstrates the subtotal occlusion of the venular lumen by collagen and extracellular matrix. (c) Immunostain Mac 387 for macrophage/monocytes demonstrates a zone of cells at the interface of the viable and necrotic hepatocytes. (d) Smooth muscle actin immunostain demonstrates marked expansion of hepatic stellate cell processes within the damaged sinusoids surrounding the venule. (For a color version of this figure, please see the color plate section.)

HCT patients treated with gemtuzumab ozogamicin (Mylotarg™), a humanized anti-CD33 monoclonal antibody conjugated to calicheamicin. The associated histology of gemtuzumab ozogamicin-associated SOS differs slightly from SOS occurring after myeloablative cytoreductive conditioning in displaying more sinusoidal fibrosis than venular occlusion (Figure 26.8) [32]. Late-developing ascites from nodular regenerative hepatocellular hyperplasia (NRH) alterations are not associated with symptoms of early liver toxicity. They most likely are secondary to disturbances in hemodynamics and serve as an indicator of compensatory repair and regeneration of hepatocytes in different zones of the liver acinus [33]. Several other conditions that may result in ascites or an SOS-like picture from diminished sinusoidal blood flow with increased sinusoidal resistance are GVHD, congestive cardiopathy [26], viral hepatitis with bridging fibrosis, occult cirrhosis, and steatohepatitis, both alcohol and non-alcohol related.

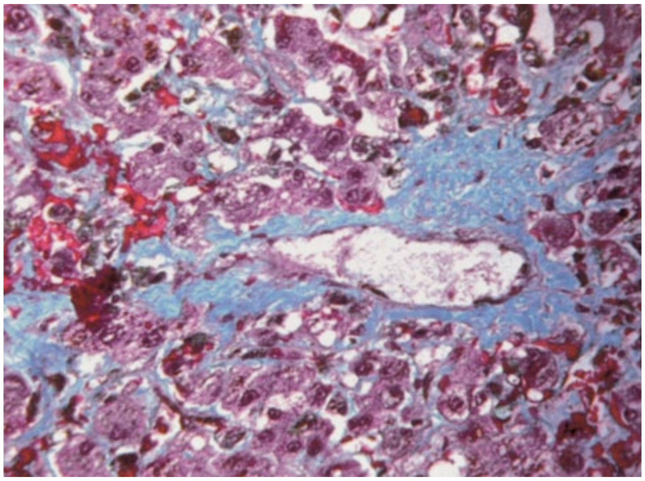

Figure 26.17 Hepatic phlebosclerosis, day 96. Eccentric thickening of the venular wall without striking luminal narrowing was associated with an early liver toxicity syndrome. The patient had received a 5-day infusion of high-dose cytosine arabinoside (Ara-C) followed by CY and TBI. Liver function abnormalities developed prior to the infusion of marrow. Changes of phlebosclerosis were widespread, but there were no identifiable hepatic SOS lesions at autopsy. (Trichrome stain.) (For a color version of this figure, please see the color plate section.)

Post-transplant hematopoietic evaluations

High-dose conditioning produces massive destruction of the host marrow, resulting in acute serous myelitis (serous atrophy) without necrosis of the bony trabeculae (Figures 26.18 and 26.19). The myelitis includes edema, hemorrhage, loss of most marrow elements except plasma and mast cells, and relative predominance of damaged and frequently necrotic fat associated with iron-rich macrophages. This damage gradually resolves over the first 4–6 weeks as colonies of donor myeloid, megakaryocytic, and erythroid precursors develop. Rarely, marrow necrosis occurs after intense cytoreduction or at the onset of leukemic relapse. The early analysis of the regenerating marrow focuses on marrow cellularity, trilineage maturation, and disease recurrence. Engraftment is usually simultaneous in the three major cell lines, although there can be considerable lag in one or more lineages. Failure or loss of donor engraftment may be manifest by the decline or absence of peripheral counts and marrow hypocellularity. Marrow engraftment following a cord blood cell transplant, especially in adults, is often delayed [34]. In rare patients with

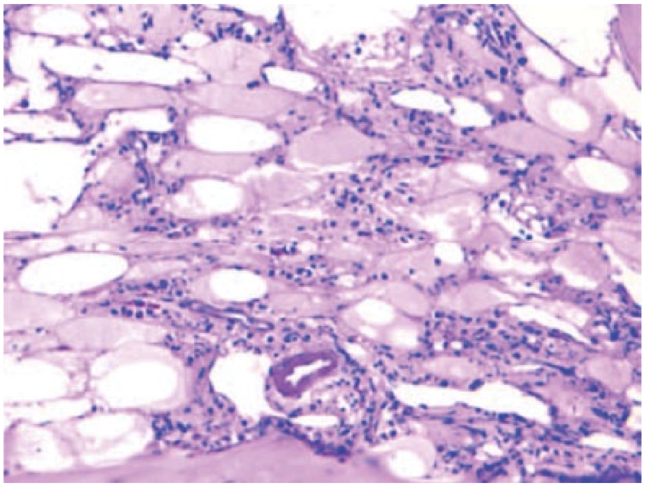

Figure 26.18 Markedly hypocellular marrow without evidence of engraftment, day 7. The interstitial fluid accumulation, fat necrosis, and iron deposition are consistent with chemoirradiation damage. (For a color version of this figure, please see the color plate section.)

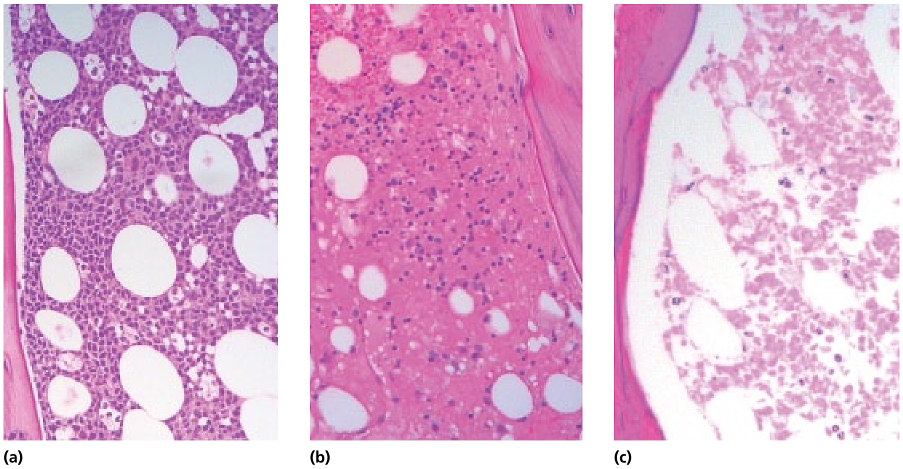

Figure 26.19 Same patient as in Figure 26.18 with acute myeloid leukemia: (a) diagnostic marrow with 96% blasts; (b) day 7 marrow after chemoreduction showing serous atrophy; (c) day 21 marrow with persistent pancytopenia showing extensive necrosis with only scattered neutrophils. (For a color version of this figure, please see the color plate section.)

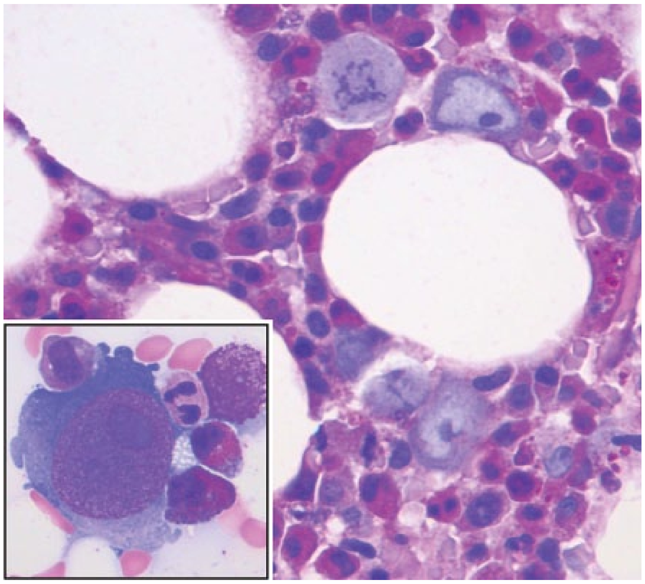

Figure 26.20 Pre-transplant marrow biopsy stained with periodic acid–Schiff (PAS) stain from a patient with diffuse large B-cell lymphoma with persistent anemia and quantitative Parvovirus virus PCR result of 13 billion. The PAS-stained marrow shows abnormally enlarged PAS negative proerythroblasts with prominent nucleoli and a marked erythroid hypoplasia. The inset at bottom left shows a Wright-stained aspirate smear with a markedly enlarged proerythroblasts with a prominent nucleoli. (For a color version of this figure, please see the color plate section.)

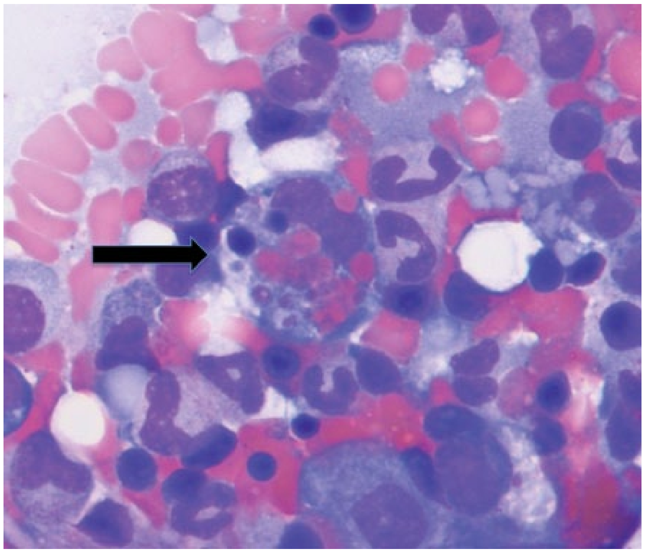

Figure 26.21 A Wright–Giemsa-stained marrow aspirate smear from a patient with large cell transformation of mycosis fungoides day 174 post-HCT with hemophagocytosis. A hematophagocytic macrophage with engulfed red blood cells and erythroid precursors in varying stages of degeneration is indicated by the back arrow. (For a color version of this figure, please see the color plate section.)

GVHD and absence of marrow hematopoiesis, there is apparently only lymphoid engraftment. Graft rejection has no specific histologic features and may be defined as transient engraftment with proliferation of at least one cell line followed by its loss. Rejection following trilineage engraftment occasionally involves loss of only a single line, analogous to pure red cell aplasia. Other causes of single- or bi lineage aplasia should also be considered in the differential for rejection, including parvovirus infection (Figure 26.20) and hemophagocytosis (Figure 26.21). Although rejection usually results in hypocellularity, this may not be true in patients being treated for some non-malignant conditions such as thalassemia or immunodeficiency. Lineage-specific chimerism testing and engraftment analysis are usually performed using PCR analysis against genomic polymorphisms termed short tandem repeat (STR) loci on lineage-sorted samples. Many laboratories fractionate the marrow by sorting separate myeloid (CD33), lymphoid (CD3), and immature (CD34) cell populations for detailed chimerism analysis (see Chapter 24). Chimerism testing is extremely important when monitoring donor cell engraftment in non-myeloablative and double cord transplants.

Despite numerous advances in the application of HCT, relapse remains the major cause of mortality [35]. Advances in MRD testing have facilitated the detection of early relapse that can then be treated with donor lymphocyte infusion (DLI) or other novel therapies. In many institutions, acute myeloid leukemia (AML) relapse is usually defined by the morphologic detection of >5% myeloid blasts. Relapse based on morphologic criteria has limited sensitivity and specificity compared with flow cytometry and molecular studies. In most cases, an increased population of malignant myeloid or lymphoid blasts cannot be distinguished from benign counterparts in a regenerating marrow by morphology alone. During marrow regeneration and with the use of hematopoietic growth factors, it is not unusual to detect an increased population of benign myeloid or lymphoid blasts (hematogones) [36]. In fact, some studies have shown that an increased population of hematogones is a good prognostic indicator in cord blood transplants of AML patients, possibly signifying a robust immune response [37]. Multiparameter flow cytometry is an essential tool since it can usually distinguish benign from malignant blasts and also identify rare aberrant blasts long before morphologic relapse is detectable [10,11]. It should be noted that in many cases there is clonal evolution and the morphology and immunophenotype of the post-transplant relapsed leukemia are different from those of the original primary pre-transplant leukemia [38]. Several studies have now shown that the presence of MRD post-transplantation is a poor prognostic indicator [39,40]. In addition, the regenerating marrow frequently shows left-shifted atypical to dysplastic features by morphology that should be interpreted with caution prior to diagnosing relapsed dysplasia. Ancillary studies including multiparameter flow cytometry, cytogenetics, and molecular testing can help determine if the atypical cells are due to marrow regeneration or relapse. In rare instances, leukemic relapse is donor derived [41,42]. Donor-derived leukemias can be easily overlooked because the relapsed leukemia may not be subjected to chimerism testing to determine donor or host origin. This is an important, but rare, distinction that impacts subsequent therapeutic decisions, since donor-derived lymphocyte infusions may not target donor-derived neoplasm.

Allogeneic HCT is the only potentially curative therapy for myeloproliferative neoplasms, including primary myelofibrosis. Some studies have shown that increased fibrosis and osteosclerosis can lead to delayed engraftment with diminution and reversal of fibrosis within 6–12 months [43]. However, most patients with primary myelofibrosis are older (median 60 years of age at diagnosis) and are frequently excluded from consideration for HCT because of regimen-related toxicity. Reduced-intensity conditioning regimens have enabled transplants to be performed in older patients, resulting in rapid regression of bone marrow fibrosis, osteosclerosis, and even molecular remission in JAK2-V617F-positive patients. One study reported a near uniform regression of fibrosis within 1 year post-transplant with most patients showing a marked reduction within 30 days of transplant [44].

Post-transplant lymphoproliferative disorder (PTLD) is a heterogeneous disease that arises in post-transplant immunosuppressed patients. PTLD is more common in solid organ transplants than in HCT patients, possibly related to immunosuppressive regimens. PTLD is defined as a proliferation of lymphocytes or plasma cells that ranges from a polyclonal reactive process to a monoclonal lymphoma. In most instances, PTLD is associated with Epstein–Barr virus (EBV) infection and is of B-cell lineage. In HCT recipients, the primary risk factor for developing PTLD is T-cell depletion, with the intensity and duration of immunosuppression being additional contributing factors. In practice, PTLD should be suspected in the setting of adenopathy or worsening of GI symptoms despite treatment for acute GVHD (Figures 26.22 and 26.23) [45]. Serial monitoring of plasma EBV DNA by PCR is used to detect increasing viral copy numbers, thus allowing early intervention [46].

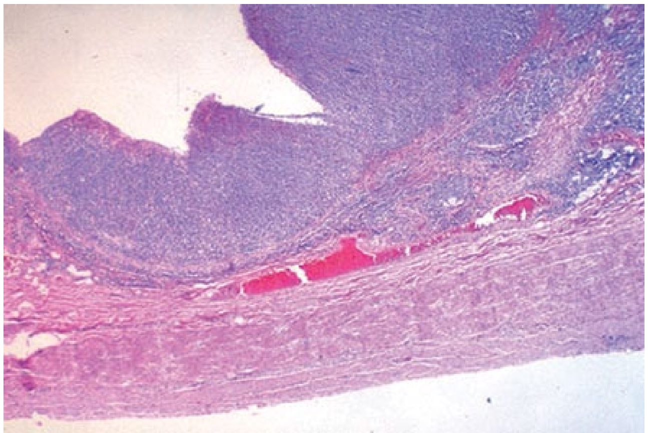

Figure 26.22 EBV-associated lymphoma infiltrating the intestinal mucosa in a boy treated for GVHD with cyclosporine and a monoclonal antibody to T-lymphocytes. Although the GVHD improved, large bizarre cells with atypical nuclei characteristic of a high-grade lymphoma rapidly formed tumor nodules in liver, spleen, lymph nodes, and mesentery. (For a color version of this figure, please see the color plate section.)

Role of the microvasculature in transplant complications

The microvasculature plays a major role in a number of post-transplant complications. Endothelial injury is the underlying cause of SOS, diffuse alveolar damage, alveolar capillary hemorrhage, immune-idiopathic pulmonary syndrome, and transplant-associated microangiopathic/hemolytic (TAM) syndrome (Figure 26.24) [47,48]. Visual methods for assessing endothelial injury include ultrastructure and immunostains for CD31, von Willebrand factor (vWF), vascular endothelial (VE) cadherin, TUNEL, and caspases. Additional blood markers in therapy-resistant GVHD include circulating endothelial cells, decreased vascular endothelial growth factor (VEGF), PAI-1, thrombomodulin, and adhesion molecules. Unresolved is whether the endothelium is damaged by cytotoxic T cells, inflammatory cytokines

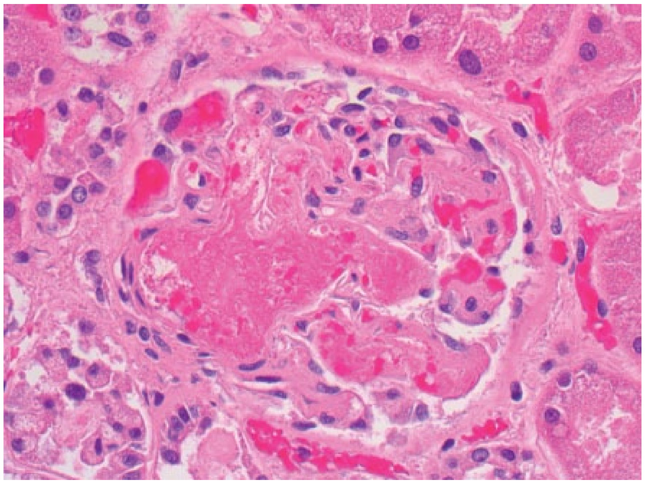

Figure 26.24 Kidney specimen stained with H&E showing transplant-associated microangiopathic/hemolytic (TAM) syndrome in a patient with AML progressed from MDS after HCT and died on day 21. There is thrombi formation in the capillary loops of the glomerulus, and characteristically showing involvement of the afferent vessel. (For a color version of this figure, please see the color plate section.)

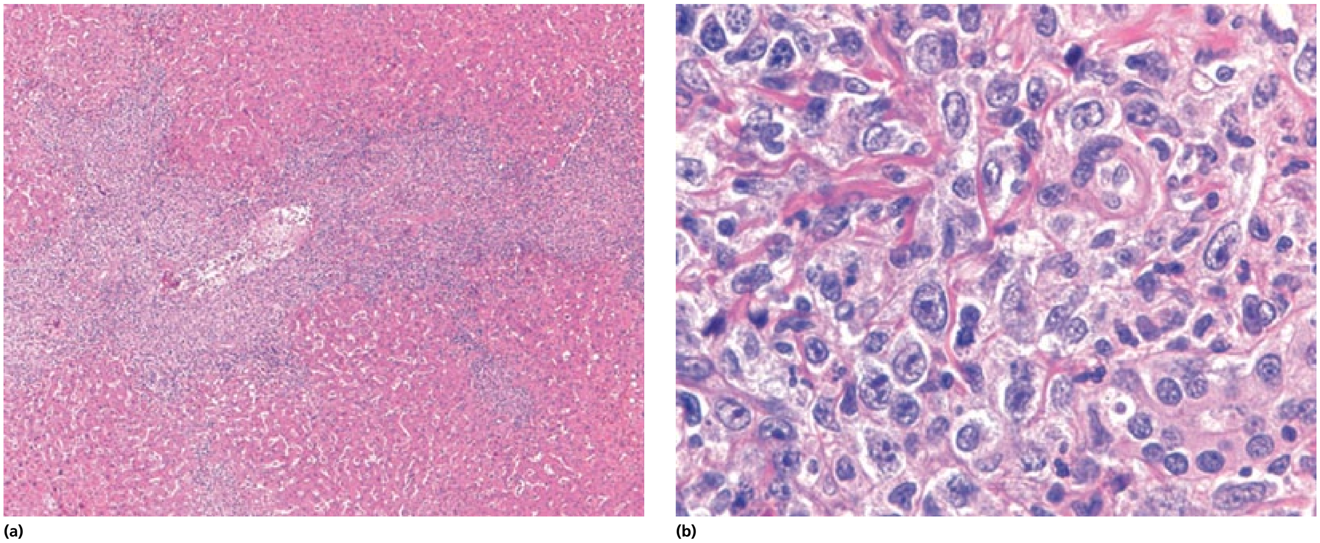

Figure 26.23 (a) Post-transplant EBV lymphoma. Following treatment for liver GVHD, the liver function abnormalities recurred. At low power, the portal space contains a prominent infiltrate that extends outwards into the periportal zone. (b) In the same case, higher magnification shows the large atypical immunoblastic cells that were positive for CD20 and EBER staining. (For a color version of this figure, please see the color plate section.)

from the inflammatory milieu and/or some combinations including the impact of certain immunosuppressive agents such as sirolimus on thrombotic microangiopathy [49,50] (see Chapter 96).

Graft-versus-host disease

The term graft-versus-host disease (GVHD) was introduced 60 years ago by Barnes and Loutit to describe diarrhea, skin disease, and wasting syndrome in irradiated mice after an allogeneic stem-cell transplant [51]. Today, GVHD continues to be the major complication of HCT that can lead to significant morbidities, infection, and death. Traditionally, GVHD has been classified into acute (occurring within the first 100 days post-transplant) and chronic (occurring after the first 100 days). The acute form is characterized by inflammation and epithelial cell apoptosis whereas the chronic form has a more pleotropic presentation, mimicking several autoimmune disorders such as scleroderma with increased tissue fibrosis. Recent changes in GVHD therapy and extended prophylaxis have created considerable overlap between acute and chronic GVHD, with late-occurring cases of acute GVHD resulting as "flares" following discontinuation of immunosuppressive regimens. Most investigators now favor the pathologic diagnosis to be based on histologic features (inflammation and apoptosis or increased tissue fibrosis) rather than time since transplant [52,53].

Immunopathogenesis

The pathophysiology of GVHD is commonly divided into two phases. In the afferent phase, there is initial tissue damage and immune activation related to the conditioning regimen. In the efferent stage, the activation of the effector cytotoxic T cells propagates the damage seen in GVHD. The classical scheme of GVHD can be subdivided into five basic steps, including priming of the immune response, T-cell activation and costimulation, alloreactive T-cell expansion and differentiation, activated T-cell trafficking, and the destruction of target tissue by effector T cells [54]. More recent studies have shown the importance of persistent B cell activation and loss of B cell tolerance contributing to and immunopathogenesis of chronic GVHD [55,56]).

GVHD can be thought of as an exuberant inflammatory response by the donor lymphocytes targeting selective host tissues and thus shares features with many autoimmune and other inflammatory conditions. The afferent or initiating stage is triggered by damaged or injured epithelium due to recent conditioning stimulating the donor lymphocyte-mediated inflammation. The damaged tissue produces proinflammatory cytokines and chemokines that result in the increased recruitment and activation of antigen-presenting cells (APCs). The APCs then present the host antigens including minor MHC antigens to the donor lymphocytes, triggering the initial phase of GVHD. Tissue damage to the GI epithelium is especially important because it results in systemic translocation of microbial products such as lipopolysaccharide (LPS) and other pathogen-associated antigens that further stimulate the APCs. The emerging influence of the intestinal microbiota and GVHD is an active area of investigation [57,58]. The observation that tissue damage from recent therapy contributes to GVHD has led to reduced-intensity conditioning as a strategy to decrease the incidence of GVHD.

The classical concept for the efferent stage in GVHD is that donor cytotoxic lymphocytes attack host cells, including some epithelial cells of the skin, intrahepatic bile ducts and gut. Electron microscopic and immunohistologic data demonstrate lymphocyte epithelial attachments and activation of infiltrating cytotoxic lymphocytes in human biopsy material. T-cell subsets, especially the regulatory T cells (Tregs), are thought to play an important role in modulating the expression and severity of GVHD. The addition of Tregs post-transplant has been shown to reduced GVHD and therapies based on this approach are currently in clinical trials [54]. In addition, patients with the rare disorder immunodysregulation polyendocrinopathy enteropathy X-linked syndrome (IPEX) lack functional Tregs owing to a dysfunctional FoxP3 transcription factor present with an autoimmune disorder, which mimics GVHD. Although HCT provides a potential cure for patients with IPEX, it is difficult to differentiate between GVHD and recurrent disease in post-transplant patients. Additional non-lymphoid cells of the innate immune system also play a role in the effector stage of GVHD, as two French studies have demonstrated that activated eosinophils [59] and apoptotic granulocytes [60] (along with TNF-α and Fas) are found in the lamina propria of GI GVHD. Similarly to many other inflammatory conditions, once triggered there are many pathways that serve to amplify and promote the inflammation, resulting in more tissue damage, apoptosis, and inflammation.

The targets of GVHD primarily involve selective epithelial cells in the skin, GI tract, liver, and lung. The specificity for these tissues is not known but may be related to the barrier function of the epithelium that is exposed to exogenous pathogens [54]. Preferential target cells reside in subregions of epithelium where cytokeratin 15 (K15) epithelial stem cells or their early progeny are located (e.g. the parafollicular bulge of the hair follicle and rete ridges of skin, and the latero-basal and neck regions in the crypt cells of gut) (Figures 26.25–26.27). In an experimental system using murine lingual epithelium, which resembles human cutaneous rete ridges, it has been shown that the genes that regulate apoptotic vulnerability are differentially expressed in a basal layer subpopulation distinguishable by K15 [61]. Recent studies by Zhan et al. demonstrated a cytokine-induced change in the CK15 stem cells from an anti-apoptotic profile to a proapoptotic profile [62]. Parallel studies have shown that the intestinal stem cells (ISCs) are targeted in GVHD, leading to an inhibition in the recovery and regeneration of the intestinal mucosa after injury. In addition, the injection of Wnt agonist R-spondin1 (R-Spo1) protected against ISC damage, enhanced restoration of injured intestinal epithelium, and inhibited subsequent inflammatory cytokine cascades. Therefore, protection of the epithelial stem cells during GVHD represents a novel strategy to decrease epithelial damage and stimulate regeneration, thus improving the outcome of allogeneic bone marrow transplantation (BMT) [63].

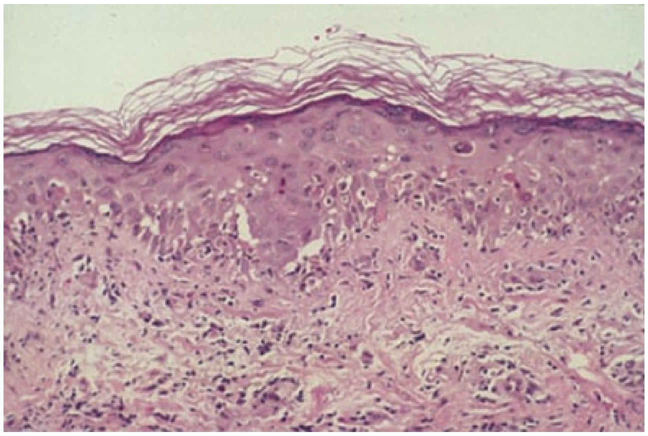

Figure 26.25 Acute skin GVHD, day 28 after mismatched allogeneic HCT. The epidermis demonstrates a prominent lichenoid reaction involving the tip of the rete ridge in the center of the specimen, a location of epithelial stem cells within the epidermis. (For a color version of this figure, please see the color plate section.)

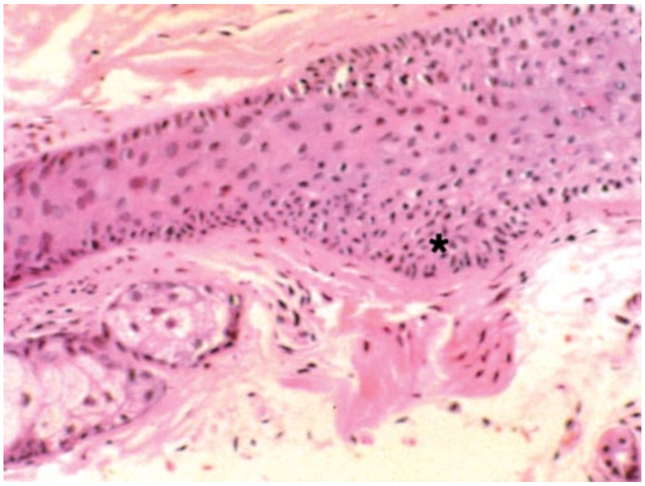

Figure 26.26 Early skin GVHD involving the parafollicular bulge region of the pilar unit. Note the small numbers of mononuclear inflammatory cells which infiltrate the parafollicular bulge area (*) near the arrector pilorum muscle in association with apoptotic bodies. (For a color version of this figure, please see the color plate section.)

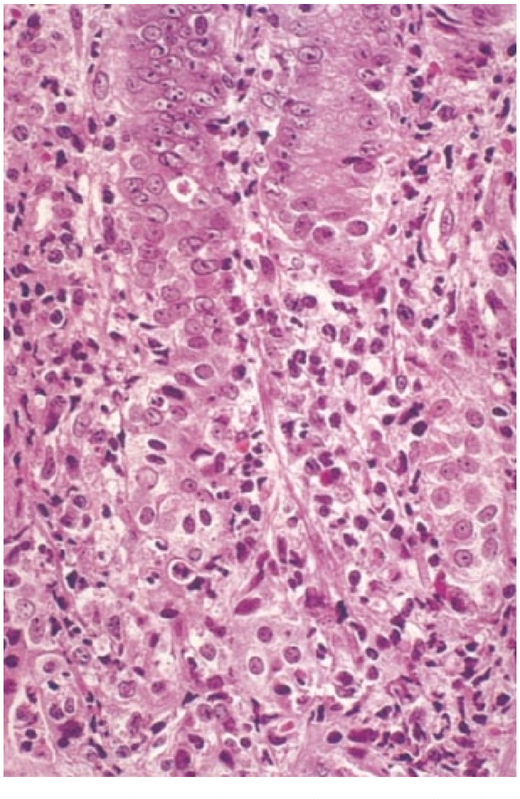

Figure 26.27 Gastric biopsy with GVHD, day 35. Several studies have shown that of all upper endoscopic biopsy sites, the stomach most frequently shows histologic changes of GVHD. In the area shown here, large numbers of lymphocytes infiltrate the lamina propria and the basilar portions of the gastric crypts. There is apoptosis of crypt epithelial cells and frank early crypt destruction. Inflammation and apoptosis of this intensity are not required for the diagnosis of gastric GVHD. More subtle yet still diagnostic alterations are illustrated in Figures 26.50 and 26.51. (For a color version of this figure, please see the color plate section.)

The initial investigations of acute GVHD focused predominately on T-cell-mediated injury of target epithelia while largely ignoring the possible involvement of B cells [56] and the endothelium, a major target in solid organ rejection. While assessing endothelial injury, it is difficult to separate non-specific activation by standard injury from selected targeting of the vessels. Early studies of dermal post-capillary venules in human cutaneous GVHD noted that endothelial damage was more marked in mismatched than matched sibling recipients [64]. The vascular endothelium serves as the gateway for lymphocytes to home through specialized addressins into the organs targeted by GVHD. The endothelial surface and homing are influenced by cytokine-mediated damage. In both the afferent and efferent stages of acute GVHD, the trafficking of naïve or programmed efferent T cells is directed by the requisite combination of homing receptors and chemokine receptors that engage the endothelium and the target tissue [54,65]. The release of serum factors affecting endothelial activation occurs in both the allogeneic and autologous setting. It reflects the collective effects of activation by chemoattractants and cytokines from conditioning and engraftment, upregulation of proinflammatory, prothrombotic, and proapoptotic state, resulting in increased permeability and cellular migration [66]. Of relevance, some drugs, such as lovastatin, may interfere with the expression of GVHD by blocking T-cell adhesion, proliferation, and cytokine production [67,68].

Immunohistology

In general, T-cell infiltrates, predominately CD8+, have been found in immunohistochemistry (IHC) studies of skin biopsies. Those few groups who have studied blood and tissue ratios of T-cell subsets simultaneously have found similar CD4/8 ratios in the peripheral blood and affected tissue. Later studies of GVHD in the skin and lip have shown that the infiltrates are primarily cytotoxic T cells as defined by CD8, the cytotoxic marker TIA-1, and perforin. Two studies found that increased numbers of CD163+ cells (macrophages) in human skin GVHD were variably associated with steroid refractoriness [69,70]. Increased numbers of donor and host dendritic cells and donor macrophages in the skin may facilitate antigen presentation and cytokine stimulation of CD8+ T cells by sustaining the response of previously activated T cells [71]. A combined histologic, ultrastructural, and IHC study of human upper endoscopic mucosal biopsies found both TNF-α and Fas expressed in the infiltrate and a significant correlation between the number of apoptotic cells and day 90 transplant-related mortality [60]. Human studies of mucosal FOXP3 regulatory T cells reported contradictory findings. Rieger et al. [72] reported numerically reduced Tregs in GI GVHD whereas Lord et al. [73] found no relationship between the frequency of Tregs in the gut and blood and the severity of GVHD. These conflicting results may be explained by a physiological heterogeneity of Tregs; following ex vivo fucosylation of human Tregs, there is both enhanced persistence and anti-GVHD potency [74]. In a study focusing on repair and regeneration of GVHD-induced damage, Murata et al. demonstrated both keratinocytes and dermal endothelial cells of donor origin by using TUNEL and XY fluorescence in situ hybridization (FISH) staining of skin biopsies from sex-mismatched HCT recipients [75]. The donor-derived cells were most numerous in the areas of severe GVHD damage, and only present in patients with a history of GVHD. However, the implications for any subsequent repair of GVHD-damaged tissues is unclear since the switch from recipient to donor phenotype was present only in biopsies taken early and not later during the course of GVHD.

In the clinical setting, the use of IHC for routine diagnosis of GVHD is limited by the sparseness of lymphoid infiltrates, additional delay and expense, lack of control data for other inflammatory conditions in the transplant milieu, and variations in the GVHD effector cell immunophenotype. There are limited data comparing apoptosis markers such as activated caspase 3 to hematoxylin and eosin (H&E) stains in both GVHD and relevant non-GVHD inflammatory conditions [76]. Little has been published on the use of IHC staining with C4d, a marker of complement activation in GVHD [77].

Surgical pathology of GVHD

Certain problems or controversies in the pathology of GVHD persist. There is still a histologic overlap between early conditioning toxicity, certain infections, and GVHD in the skin and gut. Defining the minimal threshold for early GVHD diagnosis or after prolonged immunosuppressive therapy remains a challenge. There is variance in the criteria for minimal activity consistent with active GVHD, particularly for the gut, when biopsies are obtained early after the onset of symptoms or during ongoing immunosuppressive therapy. In addition to false-positive diagnostic interpretations from concurrent viral infections and drug or conditioning toxicity, the inverse situation of false-negative biopsies exists, particularly when biopsies are obtained soon after the onset of rash or GI symptoms. Furthermore, in the GI tract there is discrepant opinion on whether the gold standard for GVHD diagnosis should be based on the broad visual survey seen by endoscopy, clinical features, or the microscopic examination of small biopsies [78].

The 2005 NIH Pathology Consensus Committee's minimal histologic criteria for GVHD by organ system are reproduced in Table 26.1 [53]. The updated table in the 2014 NIH consensus includes minor changes in the lung and inclusion of the kidney [1]. While the basic pathology of GVHD is apoptosis and eventually destruction of selective targeted epithelia with or without fibrosis, there are a number of factors that can influence or cause difficulty in interpretation. These include residual toxicity from conditioning, immunosuppressive treatment that blunts inflammation, a key indicator of activity, coexisting infections, and drug reactions that

Table 26.1 Histological Criteria for GVHD by Organ System

Organ or System	Minimal criteria for acute/active GVHD*	Specific criteria for Chronic GVHD[†]
Liver	Global assessment of dysmorphic or destroyed small bile ducts ± cholestasis, lobular and portal inflammation	Ductopenia, portal fibrosis, chronic cholestasis reflect chronicity but are not specific for chronic GVHD
Gastro-intestinal	Variable apoptotic criteria (≥1/piece) in crypts	Destruction of glands, ulceration or submucosal fibrosis may reflect severe or long-standing disease but are not specific for chronic GVHD
Skin, in general	Apoptosis in epidermal basal layer or lower Malphigian layer or infundibulum/outer root sheath/hair bulge of hair follicle or acrosyringium/sweat ducts ± lichenoid inflammation ± vacuolar change ± lymphocytic satellitosis	
Skin lichen planus-like		Combination of epidermal orthohyperkeratosis, hypergranulosis and acanthosis resembling lichen planus ± lichenoid inflammation and / or vacuolar changes of eccrine units
Skin morpheic (localized or diffuse		Thickening and homogenization of collagen bundles throughout reticular dermis or pandermal sclerosis with overlying interface changes ± thickening and homogenization of subcutaneous septa
Skin lichen sclerosus- like		Homgenization ± sclerosis of papillary dermal collagen with overlying interface changes including melanophages in the papillary dermis and sparse lymphocytic infiltrate
Skin fasciitis		Thickening of fascial septa with adjacent inflammation ± sclerosis of subcutis
Oral/ oropharyngeal mucosa and conjunctiva	Lichenoid interface lymphocytes with infiltration of mucosa (exocytosis) and variable apoptosis[‡]	
Minor salivary or lacrimal gland		Periductal lymphocytic infiltrate with infiltration and damaged intralobular ducts, fibroplasia in periductal stroma, mixed lymphocytic and plasmacytic inflammation with destruction of acinar tissue[§]
Lung		Constrictive bronchiolitis obliterans: dense eosinophilic scarring beneath the respiratory epithelium, resulting in luminal narrowing or complete fibrous obliteration. May be preceded by lymphocytic bronchiolitis without intraluminal fibrosis[¶]
Kidney		Membranous nephropathy, Minimal Change Disease
Lesions of Uncertain Pathogenesis		
Lung		Cryptogenic organizing pneumonia
Skeletal Muscle		Myositis

*Conditions that result in lesser degrees of change include immunosuppressive treatment, biopsy very soon after onset of signs, suboptimal or small tissue sample, insufficient serial sectioning, confounding infection, drug reaction or inflammatory conditions.

[†] After the diagnosis of chronic GVHD has been established or following immunosuppressive treatment, the histological manifestations of active disease may meet only minimal diagnostic criteria for activity. Different manifestations of cutaneous chronic GVHD may all be present together in one biopsy or in separate but concurrent biopsies

[‡] Inflammation of the oral mucosa and within the minor salivary glands may persist from prior chemo-irradiation or prior inflammation. The distinction between acute and chronic GVHD requires the addition of distinctive oral manifestations [81].

[§] The distinction of past acinar destruction and fibrosis from ongoing chronic GVHD activity can be difficult and relies on assessing lobules that are not completely fibrotic. Acinar and periductal inflammation with features of damage to ducts, such as vacuolar change, lymphocytic exocytosis nuclear dropout, dyspolarity or apoptosis, and resultant fibroplasia indicate chronic GVHD activity.

[¶] Constrictive bronchiolitis obliterans (CBO) [179,189] should be distinguished from cryptogenic organizing pneumonia [176,177], which is also associated with GVHD but has a different clinicopathologic presentation and a more favorable outcome.

Reproduced with permission from Shulman et al. *Biology of Blood and Marrow Transplantation* 2015 **21**: 589–603 [1a].

can mimic GVHD. The timing of the biopsies, sampling error (especially with gut biopsies), and technical factors can cause a false-negative histologic assessment. Furthermore, the diagnostic standards for minimal criteria for GVHD are inexact regarding the minimum required number of apoptotic epithelial cells, whether their presence is necessary in mucosal biopsies with inflammation, the number of serial sections needed to exclude a false-negative diagnosis, and the extent of dysmorphic change for a positive diagnosis in salivary and bile ducts. As a result, histologic examination may not always be the gold standard for diagnosis. In reality, the histologic changes, especially in patients undergoing immunosuppressive treatment for GVHD, are often not pronounced; a biopsy can be interpreted as GVHD with mild activity and confounding conditions. The pathology report can convey these issues by integrating the histologic findings with the relevant clinical details in a comment and by inserting qualifying phrases, the implication of which is understood within that institution, into the final diagnosis (e.g. possible, consistent with, favor). In the final analysis, the decision to treat for GVHD is made by the clinician based on a number of factors, including the likelihood of relapse and the desirability of a graft-versus-tumor effect, clinical stage of the target organ abnormality, rapidity of progression, the toxicity of treatment, and the histologic findings [79].

Acute versus chronic GVHD

Advances in HCT practice have altered the manifestation and separation of acute and chronic GVHD [52,53,80] (Table 26.1). The clinical manifestations [52,80] and certain unique histologic changes [53] listed in Table 26.1 are the minimal criteria that define acute and chronic GVHD. The NIH clinical classification identifies an overlap syndrome, which is a composite of both acute and chronic features. The classification also includes acute GVHD that is persistent, recurrent, or occurs after day 100 without meeting additional diagnostic criteria for chronic GVHD [81,82]. Tissue biopsies are used as a primary biomarker for establishing the diagnosis and type of GVHD, for assessment of activity to monitor therapy, and as a tool for prognosis. Pathologists should be familiar with the changing histologic spectrum of GVHD [53,80], and have an awareness of relevant clinical data and questions surrounding a biopsy. Protocols for guiding histologic evaluation and clinical information relevant for interpretation from skin, liver, gut, and mucosal biopsy sites are available online at the American Society Blood and Marrow Transplantation: http://www.asbmt.org/?page=Histopathology; http://www.asbmt.org/?page=MeasureCGVHD.

The incidence of chronic GVHD over a 12-year period has shown a steady significant increase to 37% between years 2004–2007 [83]. Physical evaluation of the skin in chronic GVHD has been standardized [84] and assessment of progression and prognosis have been validated through a combination of the NIH composite skin score and the Lee patient symptom score [2]. The histologic changes specific for chronic GVHD occur in the biopsies from skin and fascia, salivary and lacrimal glands, muscle, and lung. There is no clear histologic dichotomy between acute and chronic GVHD in the liver or gut. From the pathologist's viewpoint, chronic GVHD is a multiorgan inflammatory disorder that resembles a mixture of GVHD and several autoimmune diseases and rejection after solid organ transplantation.

Clinical and experimental data indicate that clonotypic T-cell effectors that mediate chronic GVHD have a unique specificity that includes tissue targets against donor and self [85]. One explanation for this observation is the destruction of thymic epithelium by acute GVHD effector T cells resulting in failure to detect autoreactive T cells (Figure 26.28). The contribution of microvascular damage in the genesis of the dermal fibrosis of chronic GVHD is controversial. Biedermann et al. found a correlation between elevated blood vWF levels and reduced capillary density identified by immunostaining for *Ulex europaeus* to the dermal sclerosis in chronic GVHD [86]. They concluded that reduced vascularity was responsible for the fibrosis and further inferred that the presence of T cells in the perivascular zone suggested that the endothelium was the target. In contrast, Fleming et al. did not find a correlation between the dermal fibrosis in chronic GVHD and a reduction in dermal capillary density. They also showed that the microvasculature in chronic GVHD did not have the abnormal endothelial phenotype of reduced VE cadherin and vWF [87] nor the abnormal capillaroscopic appearance characteristic of capillaries in systemic sclerosis [88].

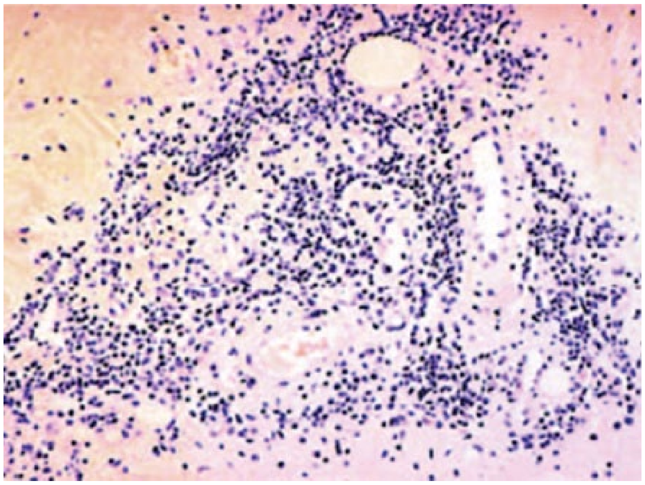

Figure 26.28 Atrophy and fibrosis of thymus associated with chronic GVHD in a 13-year-old, day 350. The patient had not received immunosuppressive drugs, so the destruction was presumably the result of chronic GVHD activity. (For a color version of this figure, please see the color plate section.)

The importance of screening biopsies at day 80–100 to identify histologically active GVHD of skin or lip in asymptomatic patients still on immunosuppression is less relevant. A positive screening biopsy (after day 100) with evidence of active GVHD (i.e. apoptotic epithelial cells) but devoid of the histologic features of chronic GVHD is no longer considered to be chronic GVHD. Likewise, a positive screening oral biopsy unaccompanied by distinctive gross oral features of chronic GVHD is no longer classified as chronic GVHD [52,53]. Accordingly, there is a wide spectrum of utilization of oral and skin biopsies in the diagnosis and management of late acute or chronic GVHD [82,89]. Biopsies are recommended to confirm active chronic GVHD when alternative diagnoses are entertained, the clinical signs are confined to internal organs, or the clinical assessment of activity is obscured by prior changes. In one tertiary care center, 7% of patients sent for consultation regarding chronic GVHD had been incorrectly diagnosed and treated for active chronic GVHD before referral [90].

Grading of GVHD

The initial histologic grading system of Lerner et al. was devised in 1974, with conditions far different from those today [91]. The scheme had four histologic grades for acute GVHD in the skin, liver, and gut, which attempted to use the chronologic progression of injury as a scale of severity based on the amount of inflammation, apoptosis, and the degree of tissue damage. In fact, GVHD histology is a snapshot in time such that mild (grade I) or severe (grades III–IV) changes may primarily be a reflection of timing and duration of activity (stage) and degree of immunosuppressive treatment. The Lerner scheme and other subsequent histologic grading schemata for GVHD were created without first being verified against useful clinical end-points. The lower histologic grades, II in the skin and I in the gut, still serve as benchmarks for defining minimal diagnostic criteria. In contrast, the higher grades of skin GVHD are rarely encountered. Serologic liver tests may provide a more accurate gauge of response to treatment than histologic damage to the biliary system, which is much slower to show improvement. A histologic grade with a high level of inflammatory and/or apoptotic activity is highly relevant information that will impact current treatment decisions [30,53]. Persistent grade IV-gut histology, particularly in the small intestines, portends refractoriness and potentially lethal GVHD [78,92]. Nonetheless, an accurate prediction on overall outcome can be made using non-invasive clinical signs of persistent bloody diarrhea with refractoriness to steroids [93]. In addition to avoiding the need to repeat the endoscopic biopsy, it also avoids the interpretive issue of whether the gut has had adequate time to show histologic improvement. Evidence-based observations indicate that time to recovery is proportionate to the severity (stage) of the destruction of the gut mucosa and/or bile ducts [26,53]. Whereas skin histologic grading schemata have limited independent prognostic value in the current milieu, the stage of cutaneous GVHD, acute or chronic, carries important therapeutic implications. These comments and those in the sections below are not meant to dismiss the use of biopsies for GVHD but rather to point out the nuances in their interpretation, and how they are currently used as a diagnostic modality or to complement clinical data.

Skin

Utility of skin biopsies in GVHD

The primary utility of skin biopsies in patients who have undergone recent HCT is to aid clinical diagnosis for GVHD and infection from other conditions such as drug eruption. It is important to identify pre-transplant diseases since GVHD has morphologic overlap with autoimmune disorders, connective tissue diseases, dermatomyositis, and many other skin rashes. In the early post-transplant setting, skin rashes are common and considered to be multifactorial. The management of early skin rashes is influenced by a set of variables, including the sex and degree of donor match, whether conditioning is myeloablative, desirability of graft-versus-tumor effect, extent of rash, rapidity of progression, and protocol requirements. In a study with a large cohort of 809 consecutive patients, 265 (33%) developed clinical grade II–IV GVHD; 27% of these had an early-onset acute GVHD manifested by day 14, referred to as hyperacute GVHD, and 88% of the patients with hyperacute GVHD had severe skin involvement with a higher non-relapse mortality, especially in recipients of unrelated donors (matched or mismatched) [79].

In previous editions, we advocated serial skin biopsies to aid in the interpretation of early skin rashes and GVHD was considered likely if the changes progressed without treatment or remained grade II or higher. Although this approach still has validity, a common alternative approach is to give a short course of steroids without first obtaining a biopsy. Sustained resolution implies that the cause is not GVHD, whereas no response or a recurrence suggests GVHD. There is no simple answer to this conundrum of when to use skin biopsies to diagnose early GVHD. The predictive utility of skin biopsies rests primarily in their display of continued histologic signs of activity rather than grade per se. Firoz et al. addressed this conundrum in a study using a decision analysis model to estimate the value of skin biopsy in the evaluation of a hypothetical case of a morbilliform rash covering 60% of the body surface status post allogeneic stem-cell transplant [94]. Ten experts provided their estimates of the prevalence of GVHD, the sensitivity and specificity of the skin biopsy, and the potential outcomes from treatment or observation. Only 25% of the experts chose an intervention consistent with their estimates of the prevalence, test characteristics (histologic results), and outcome evaluations. In this decision analysis modeling, the best patient outcome occurred if biopsy was done when the prevalence of GVHD was <30%, whereas treatment for GVHD was given without biopsy if the prevalence of GVHD was >30% [94]. The NIH consensus development project on criteria for clinical trials in chronic GVHD recommends that skin biopsies should be used to confirm active chronic GVHD when the clinical picture is unclear, another diagnosis such as infection is suspected, clinical signs of chronic GVHD are confined to other organs, only distinctive features of GVHD are seen, or the clinical assessment is obscured by prior changes [53].

The use and timing of skin biopsies for diagnosing GVHD have wide institutional variation. Depending on the patient population and, thus, the pretest probability for GVHD, the use of skin biopsies to aid in confirming GVHD may be of high importance. Some centers use skin biopsies routinely for GVHD screening, diagnosis of GVHD, and as a tool to track improvement with therapy or to detect treatment-refractory GVHD. However, other centers avoid using skin biopsies based on studies that conclude acute GVHD is histologically indistinguishable from other causes of rashes [95,96], viral infections, drug reactions, engraftment syndrome associated with lymphocyte recovery [97,98], and toxicity from pre-transplant cytoreductive conditioning [95,96,99].

Grading of GVHD in the skin

The cutaneous histologic grading system of Lerner et al. [91] has provided a useful framework for discussing minimal diagnostic criteria and the specificity of histology for GVHD. Grade I is superficial perivascular dermatitis with epidermal basal cell vacuolization; grade II is an interface dermatitis with scattered apoptotic or dyskeratotic keratinocytes in the basilar or lower spinosum layers that sometimes is in close contact with infiltrating lymphoid cells (lymphocytic satellitosis) (Figures 26.29 and 26.30); grade III has extensive apoptosis with reticular degeneration, destruction of the basal layer with nuclear dyspolarity and atypia, and suprabasilar bulla formation (Figures 26.25); and grade IV is represented by ulceration of the epidermis [92] (Figure 26.31). Distinction of GVHD from a variety of conditions is problematic and not always resolved by using grade II change for the minimal diagnostic criteria [80,95,96,99]. Clinical images of acute skin GVHD before and after PUVA therapy are illustrated in Figure 26.32.

Differential diagnosis of Grade I/II GVHD

Skin biopsies in HCT patients with grade I and II GVHD may show minimal cellular infiltrates and infrequent apoptosis (Figure 26.30). The most common differential of lower grade GVHD includes drug reaction, eruption of lymphocyte recovery syndrome, another pre-existing skin condition, or infection. Although various

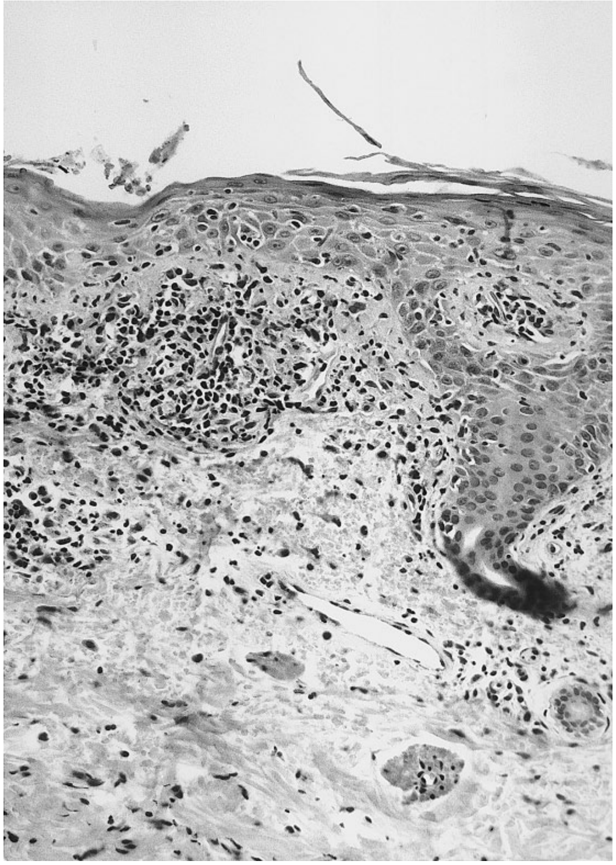

Figure 26.29 Skin, acute GVHD, day 30. Marked lichenoid reaction involving the epidermis and acrosyringium with intraepidermal lymphocytes, apoptosis, and destruction of rete ridges. (H&E.)

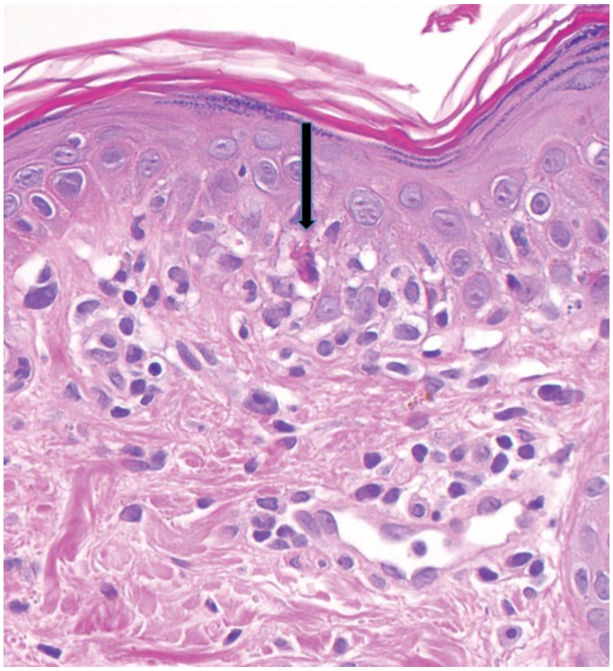

Figure 26.30 H&E stain of a skin biopsy from a, HCT patient day 25 with GVHD. There is mild spongiosis, basal vacuolization, lymphocytic inflammatory cells, and a few scattered apoptotic cells (arrow). (For a color version of this figure, please see the color plate section.)

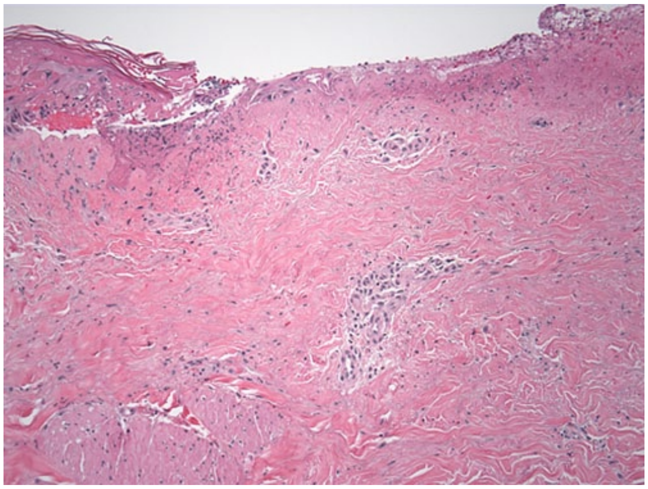

Figure 26.31 Skin biopsy with ulcerated epidermis from a patient with severe combined immunodeficiency disease, post-allogeneic stem cell transplant, day 475. The histology of this skin biopsy raised the differential of acute graft versus host disease or toxic epidermal necrolysis. (H&E.)

viral etiologies, including HHV 6, have been suggested for some of these early rashes, studies have shown evidence of increased association between HHV 6 and GVHD [100–102].

To favor a diagnosis of GVHD, it is important to review serial sections looking for apoptosis along the outer root sheath of hair follicles, the basilar layer of the epidermis, and at the tips of rete ridges. Additionally, apoptosis and architectural disarray in the eccrine units also provide support for the diagnosis of GVHD.

Drug hypersensitivity should be considered a possibility, especially if the rash has an atypical pattern or distribution for GVHD. An eczematous pattern of spongiosis with abundant lymphocytes and little or no apoptosis suggests a drug reaction rather than GVHD. Frequently, drug reaction presents with a pronounced perivascular inflammation in the superficial dermis without significant epidermotropism. Tissue eosinophils in the infiltrate are not an indication of a drug eruption as they are often also found in GVHD [103]. Drug eruption rashes frequently resolve spontaneously, and the exact causative agent is difficult to identify owing to polydrug regimens. Histology is non-specific, with perivascular inflammation edema and dilatation of the vessels.

Patients with eruption of lymphocyte recovery syndrome present with a maculopapular rash approximately 14–21 days after treatment with cytotoxic therapy that coincides with recovery of lymphocytes in the peripheral blood [104]. This rash will spontaneously improve without treatment or following withdrawal of medications [97,98]. Histology of these skin biopsies consists of scant superficial perivascular lymphocytic inflammation and vascular dilatation, with little or no keratinocyte apoptosis.

In patients who have received a busulfan-conditioning regimen, severe keratinocyte dysplasia (SKD) is a common finding, reported in up to 92% of HCT recipients [105]. SKD has been reported in HCT patients from day 28 to day 84 post-HCT; and has distinct histology compared with GVHD, although they may be seen concurrently [106]. The histologic appearance of SKD is characterized by keratinocytes with large and irregular nuclei, but may be seen in the background of GVHD (Figure 26.33).

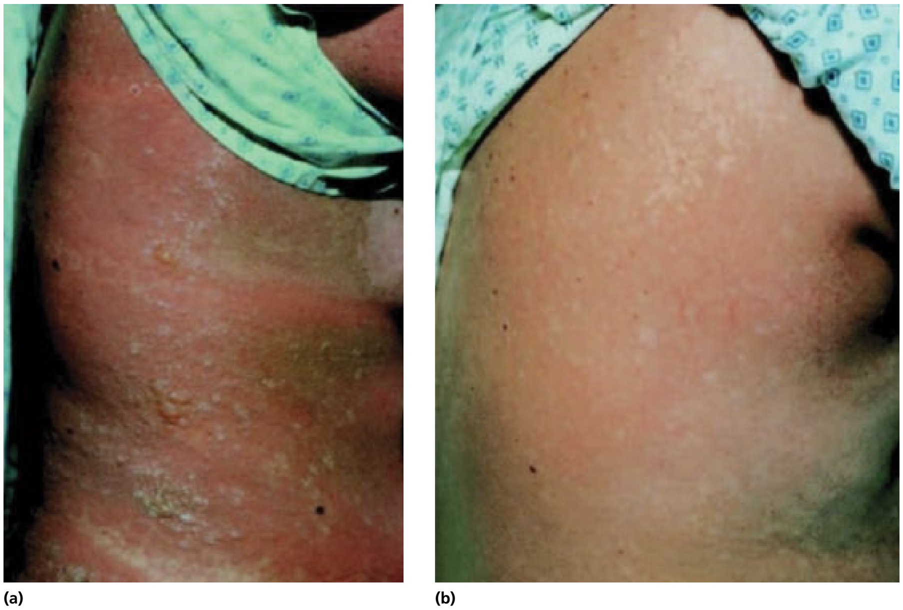

Figure 26.32 Before and after therapy photographs of the right lateral torso from the two different time points in an HCT patient: (a) erythema and desquamation before treatment for acute GVHD, day 27; (b) virtually normal skin with focal depigmentation after treatment for acute GVHD, day 74. (For a color version of this figure, please see the color plate section.)

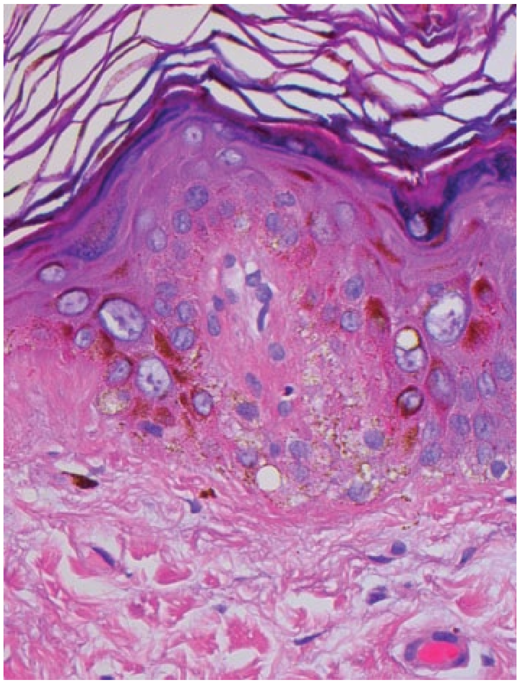

Figure 26.33 Severe keratinocyte dysplasia in a patient with myelodysplastic syndrome who is day 76 after myeloablative HCT with busulfan-based chemoreduction therapy. (For a color version of this figure, please see the color plate section.)

Differential diagnosis of Grade III/IV GVHD

The features associated with grade III/IV GVHD include extensive keratinocyte apoptosis, destruction of the basal layer causing separation of the dermal–epidermal junction, erythema, desquamation, or ulceration of the epidermis (Figure 26.24). Varying degrees of keratinocyte atypia may also be seen. These histologic findings raise the differential of erythema multiforme, toxic epidermal necrolysis (TEN), or severe drug reaction/Stevens–Johnson syndrome (SJS). A clear histologic distinction between these entities has not been established. Chemotherapy-induced acral erythema is also a differential that pathologists encounter in the early post-transplant period with a similar histology to higher grade GVHD. HHV 6 reactivation causes a rash with overlapping morphology to GVHD [107].

Erythema multiforme is an episodic self-limiting rash with varied clinical presentation ranging from macules and papules to vesicles and bullae. As expected, the variation in gross morphology also translates into varied histology with many overlapping features of higher grade GVHD, including frequent apoptosis, epidermal spongiosis, basal vacuolar change, lichenoid lymphocytic infiltrate, and clefting of the dermal–epidermal junction. In contrast to GVHD, eosinophils are generally not considered a prominent component of the inflammatory infiltrate in erythema multiforme. However, isolated case reports have shown that cases of eosinophil-rich erythema multiforme are possible [108]. The severe drug eruption producing a clinical picture of SJS or TEN with suprabasilar bullous formation and denudation can be difficult to distinguish from severe GVHD (Figure 26.34).

Chemotherapy-induced acral erythema is a syndrome of painful cutaneous acral erythema involving the palms and soles that is a distinct clinical entity caused by cytoreductive conditioning [109]. Histologically, this toxic injury to the epithelium cannot be clearly distinguished from GVHD (Figures 26.1 and 26.25). Both may display varying degrees of epidermal keratinocyte atypia, vacuolar damage, dyskeratosis, apoptosis, and interface inflammation, and depending on the particular myeloablative-conditioning regimen used, waiting 20–30 days before using the skin biopsy was advocated [96,99].

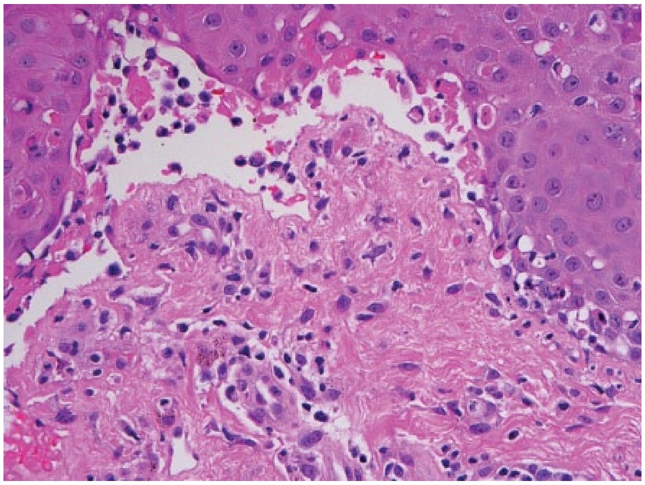

Figure 26.34 Skin biopsy from a patient who is day 36 after HCT with an erythematous non-pruritic rash involving 40% of the total body surface including the upper trunk, arms, head, and a few spots on the legs. This biopsy shows confluent basal cell necrosis with separation at the dermal epidermal junction, a histologic pattern more consistent with Stevens–Johnson type of drug eruption. (For a color version of this figure, please see the color plate section.)

(For a color version of this figure, please see the color plate section.)

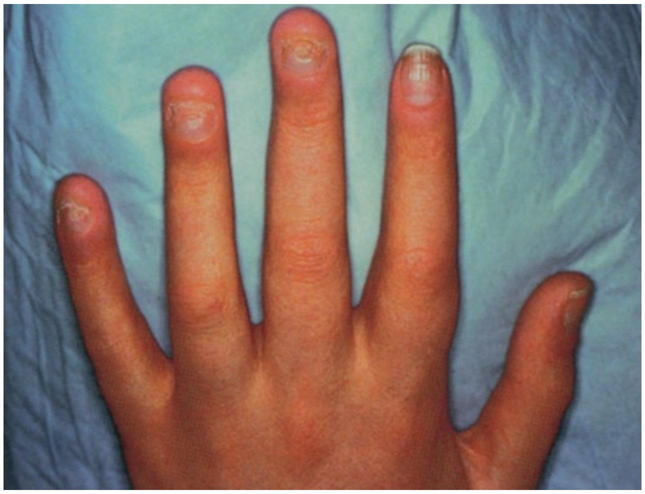

Figure 26.35 Periungual erythema and onychodystrophy 100 days after allogeneic BMT in a patient with ocular sicca and oral lesions of chronic GVHD. (For a color version of this figure, please see the color plate section.)

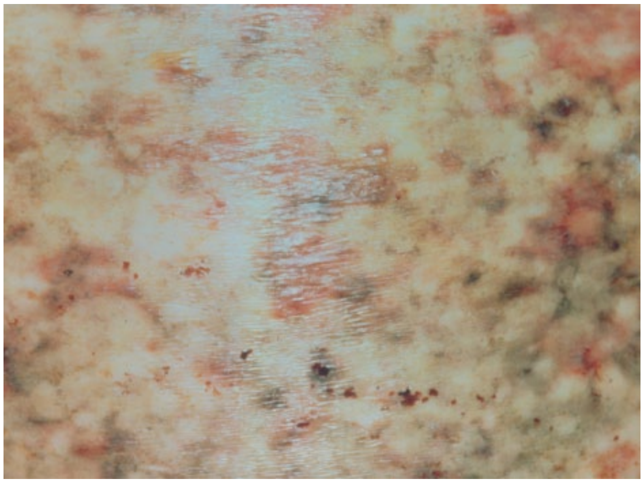

Figure 26.37 Poikiloderma in late chronic GVHD in a 2-year-old girl, day 450. Thinning of the epidermis and dermis is present along with telangiectasia and reticulated pigmentation. (For a color version of this figure, please see the color plate section.)

Chronic GVHD of the skin

Chronic GVHD of the skin has a polymorphous gross appearance potentially involving all regions, including the nails (Figures 26.35–26.37). A detailed glossary of the gross cutaneous manifestations along with a standardized nomenclature and their likely underlying histopathology may prove useful in correlating appearances with the outcome and response to therapy [80,110] The pathologist should be mindful of several caveats pertinent to the histopathology of chronic GVHD:

1 The histopathology changes over time. Usually, the predominant features of the early manifestations, referred to as lichen planus-like GVHD (Figure 26.38), are lymphoplasmacytic inflammation involving the epithelium and tubuloalveolar glands in the eccrine, lacrimal, and aerodigestive tracts. Unlike acute GVHD, chronic GVHD causes extensive destruction of these tubulo-alveolar glands and ducts with corresponding clinical sicca syndromes (Figure 26.39).
2 In later stages, referred to as sclerodermoid GVHD, there may be widespread fibrosis, stenosis, obliteration, or atrophy of the tissues involved (Figure 26.40; see also Figure 26.41). As a result, it may be difficult to distinguish active disease from residual fibrotic damage (Figure 26.42; see also Figure 26.43) in the absence of chronic inflammation or serial biopsies showing progression of the fibrosis. However, the initial presentation of cutaneous chronic GVHD may be primary with changes associated with the later stages of dyspigmentation and dermal sclerosis [110].

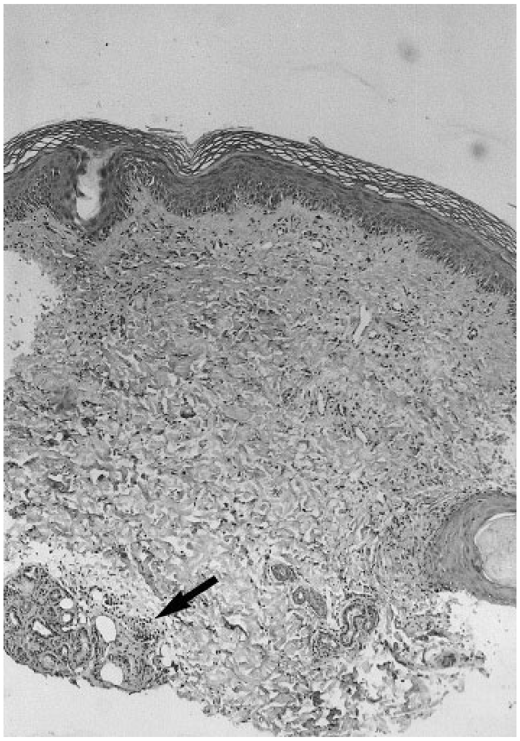

Figure 26.38 Skin, day 314, with the extensive or generalized type of early chronic GVHD. The so-called lichen planus-like chronic GVHD refers to the acanthotic and hyperkeratotic epidermis that has inflammatory and destructive changes along the dermal–epidermal junction. An eccrine unit at the base of the dermis (arrow) and a follicle deep in the dermis are also being destroyed. The dermal collagen is unaltered.

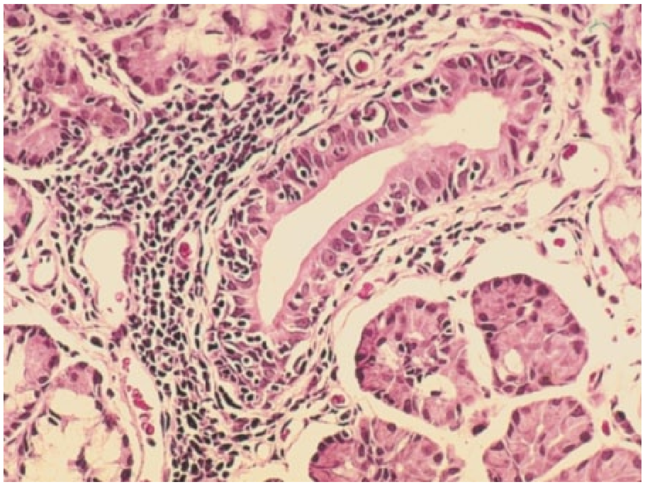

Figure 26.39 Oral labial biopsy with early chronic GVHD, day 92. The minor salivary gland exhibits a periductal mononuclear inflammatory infiltrate involving the duct epithelium, in which there is focal epithelial apoptosis. There is inflammation of adjacent acini. This process leads to fibrosis with acinar atrophy in lobules drained by the affected ducts. The squamous surface epithelium (not present here) showed grade II lesions similar to those previously illustrated in skin (see Figure 26.25). The lip biopsy is valuable in the diagnosis and staging of chronic GVHD because it frequently mirrors destructive inflammatory changes in lacrimal, tracheal, and esophageal glands as well as bile ducts. (For a color version of this figure, please see the color plate section.)

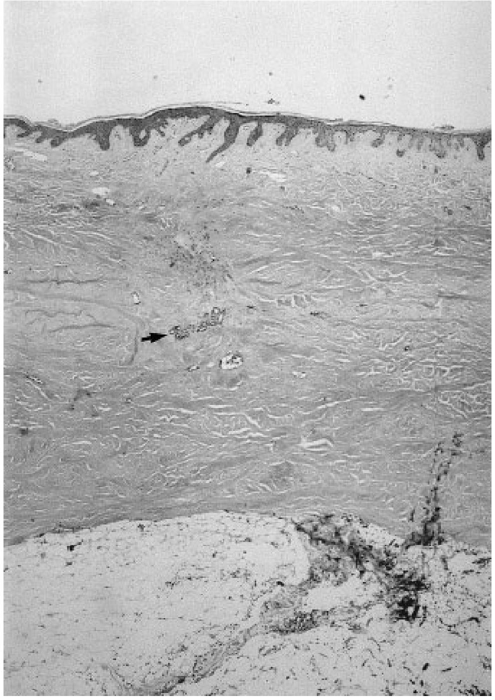

Figure 26.40 Late sclerodermatous chronic GVHD, day 910. The epidermis is atrophic. The dermal collagen is diffusely sclerotic with homogenization of the collagen, and the dermis–subcutis border is straightened. The dermis below the entrapped eccrine unit (arrow) represents acquired fibrous tissue resulting from chronic GVHD.

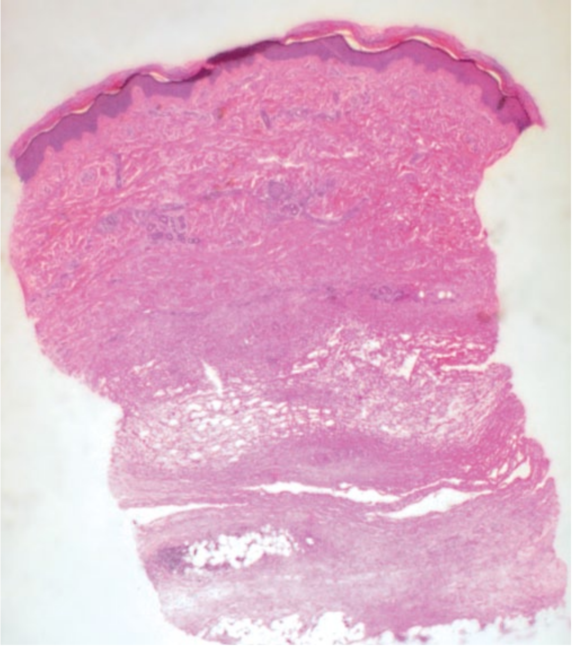

Figure 26.41 Late chronic GVHD of skin, day 959. As this patient's GVHD progressed, the epidermis became atrophic, with straightening of the dermal–epidermal junction. All dermal appendages were destroyed. The reticular dermal collagen became increasingly sclerotic. A panniculitis seen at the base of the specimen resulted in fibrosis of the subcutaneous fat and large vessels. This histologic picture corresponds to the dense hidebound and sclerodermatous changes of late chronic GVHD. (For a color version of this figure, please see the color plate section.)

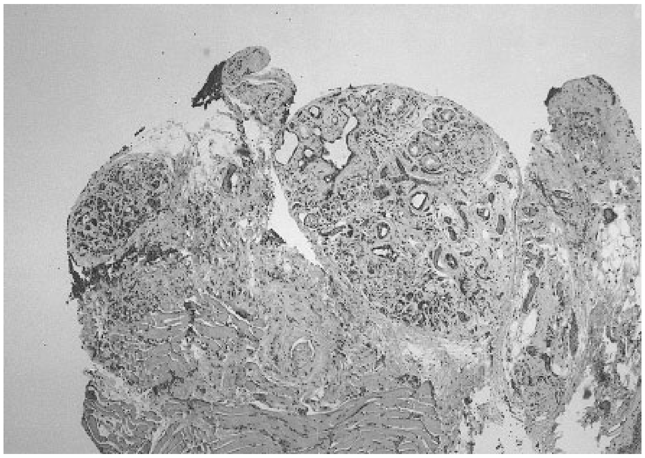

Figure 26.42 Lip biopsy, day 376. Fibrotic and destroyed minor salivary gland contains only ectatic ducts. These changes reflect previous damage from chronic GVHD. Unless they are accompanied by some inflammatory component in other glands or in the mucosa, they should not be taken as a sign of active chronic GVHD.

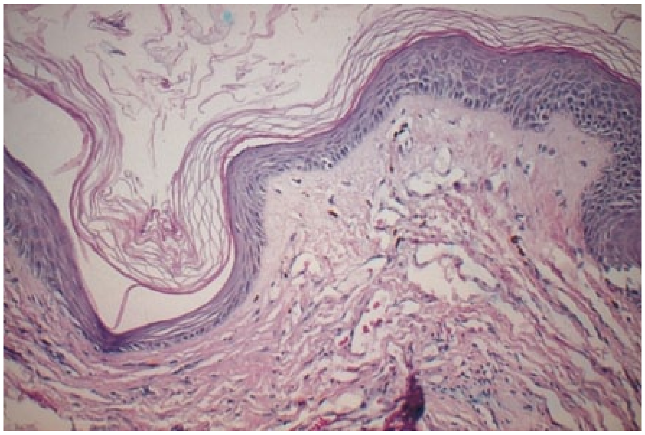

Figure 26.43 Poikiloderma, day 719. The patient was treated vigorously for extensive chronic GVHD with corticosteroids plus several other immunosuppressive agents. Although he had extensive dyspigmentation, telangiectasia, and atrophy of the skin, there were no contractures or scleroderma. Histologically, the epidermis is atrophic, with loss of rete ridges. The fibrotic papillary dermis contains many telangiectatic vessels, and there is intracellular melanin pigment. The deep dermal sweat glands remain despite earlier inflammatory involvement, and the reticular dermal collagen is normal. (For a color version of this figure, please see the color plate section.)

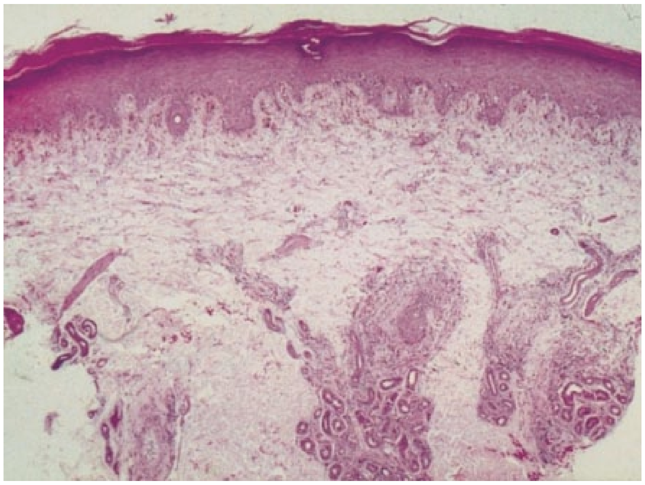

Figure 26.44 Lichenoid early chronic GVHD of skin, day 233. Biopsy of a papulosquamous lesion from the posterior neck demonstrates the characteristic features of the lichen planus-like type of chronic cutaneous GVHD. The thickened epidermis displays hyper- and parakeratosis, hypergranulosis, and acanthosis. The extensive destruction along the dermal–epidermal junction results in sawtooth-like changes of the rete ridges, mimicking lichen planus. The papillary dermis has considerable perivascular inflammation. The lichenoid reaction also involves the hair follicles and eccrine glands seen deep in the reticular dermis. At this stage, treatment can prevent progression to fibrosis (see Figure 26.41).
(For a color version of this figure, please see the color plate section.)

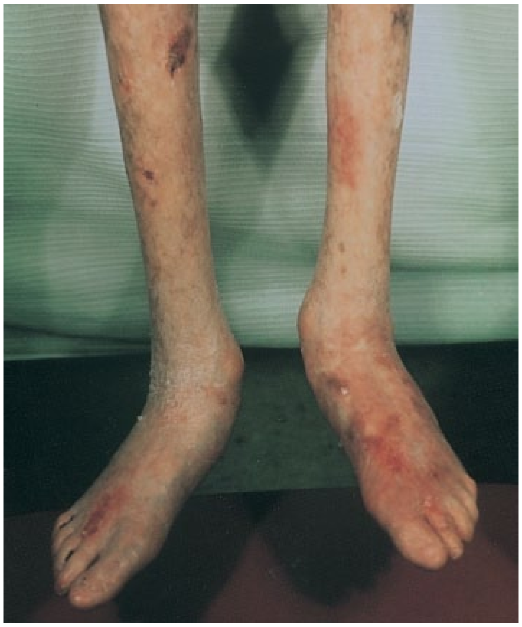

Figure 26.45 Generalized scleroderma with atrophy, sclerodactyly, and joint contracture, day 540 after HLA-identical BMT. (For a color version of this figure, please see the color plate section.)

3 Following a flare of chronic GVHD, the histologic changes may be more closely akin to those of acute GVHD. Lichenoid, sclerodermoid, and acute histologic features can coexist.

The initial dermatopathologic descriptions of cutaneous chronic GVHD were of a biphasic disorder, initially resembling a combination of widespread lichen planus and lupus profundus (Figure 26.44), which later progressed to scleroderma-like gross and histologic changes (Figures 26.40 and 26.45). Smaller subsets of patients initially present with poikiloderma, localized morpheic lesions, lichen sclerosus-like or fasciitis [111] (Figures 26.37, 26.43 and 26.46). In the current milieu, one may see various combinations of these changes plus superimposed skin lesions that only satisfy criteria for acute GVHD [52,80,90,112].

Full-thickness skin biopsies are essential to assess fully the possible changes in the eccrine units, subcutaneous fat, and fascia, and to delineate the degree of dermal fibrosis (Figure 26.41). The specific criteria for the early lichen planus-like stage are a combination of hyperkeratosis, hypergranulosis, and irregular acanthosis with

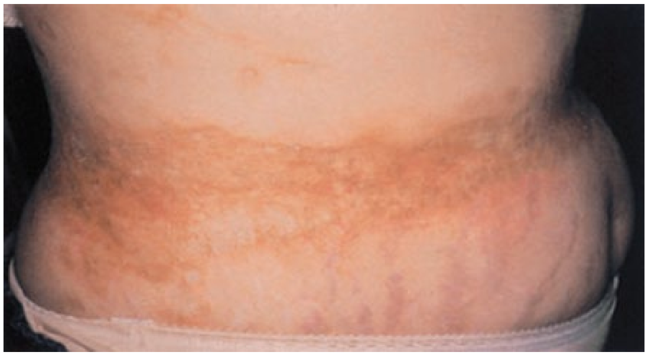

Figure 26.46 Localized late phase of chronic GVHD resembling morphea with atrophic plaque formation, induration, and peripheral hyperpigmentation, day 684. (For a color version of this figure, please see the color plate section.)

lichenoid basilar layer changes with or without syringitis (inflammation within eccrine units) or lobular panniculitis (inflammation of the subcutaneous fat) [53] (Figure 26.44). Serial biopsies demonstrate progression of fibrosis from the papillary dermis downwards, consistent with an etiology related to ongoing inflammation and release of cytokines (Figure 26.41 and 26.43). Patients with cutaneous sclerodermatous chronic GVHD, like those with progressive systemic sclerosis, have an autoantibody to the platelet-derived growth factor receptor which stimulates the activation of skin fibroblasts in vitro, suggesting a direct role in cutaneous sclerosis in both conditions [113]. However, the role of autoantibodies to platelet-derived growth factor receptor in promoting cutaneous sclerodermatous chronic GVHD is a controversial topic and not supported by all studies. The remodeling of dermal collagen progresses from straightening of the dermal–epidermal border with loss of the rete ridges and dermal appendages, along with sclerosis of the papillary and adventitial dermis with variable degrees of fibroblastic stroma. If progressive, the reticular dermis becomes thickened by smudgy collagen bundles. Eventually, the dermal–subcutaneous border becomes straightened and fibrotic septae may form in the subcutaneous fat (Figure 26.39; see also Figure 26.41). In patients receiving immunosuppressive treatment, the inflammatory changes may be minimal, with evidence of active GVHD limited to epithelial vacuolar degeneration or apoptosis in the basilar layers of the skin and its appendages, oral mucosa, or minor salivary glands of the lip.

Morpheic GVHD presents as localized dyspigmented macules with variable degrees of induration (Figure 26.46). A full-thickness biopsy demonstrates nodular fibrous remodeling in the deeper reticular dermis with variable inflammation in the dermis and adjacent subcutaneous fat. The epidermis may have minimal apoptosis or vacuolar changes. Eosinophilic fasciitis of the skin presents with an acute painful deep groove, or rippling cellulite appearance. A deep incisional biopsy shows edema and fibrosis of the fascia and subcutaneous septae with a mixed infiltrate of lymphocytes, histiocytes, and eosinophils [53,111]. A lichen sclerosis atrophicus type of chronic GVHD leads to scarring and stricture when it affects the female genitalia. Histologically, there is epidermal or mucosal atrophy with basal vacuolar changes, a band-like infiltrate associated with small numbers of apoptotic cells, and a subepidermal zone of pale homogenized collagen. Several additional forms of cutaneous chronic GVHD include eruptive angiomas, vitiligo, hyperpigmentation, destructive nail dystrophies, and ichthyosiform change [110] (Figures 26.37 and 26.45).

In contrast to assessing the development and progression of dermal fibrosis in chronic GVHD, the opposite situation pertains when hematopoietic cell transplantation is carried out for progressive systemic sclerosis. Both the clinical Rodnan dermal mobility score and the histologic scoring system for dermal sclerosis demonstrated agreement in the regression of dermal sclerosis [114,115].

Oral GVHD

Pathology of chronic oral GVHD has mucosal changes with varying degrees of lichenoid interface inflammation, exocytosis, and apoptosis. The typical differential diagnoses to consider include lichen planus, lichenoid drug reaction, and lichenoid hypersensitivity.

The assessment of GVHD in minor salivary glands should focus only on lobules that are not completely fibrotic. Active GVHD changes include lymphocytic exocytosis into intralobular ducts and acini, and lymphocytic periductal inflammation with or without plasma cells (Figures 26.40, 26.47, and 26.48). Fibroblastic periductal and periacinar stroma is indicative of chronic GVHD activity, whereas dense fibrosis indicates only previous damage (Figure 26.42). Because of residual non-allogeneic baseline inflammatory changes from myeloablative conditioning [116], there are institutional variations in how the threshold for minimal activity is defined. One such proposal with more stringent criteria requires more than three apoptotic cells in the mucosa and >10% loss of acinar tissue or ductal epithelial necrosis [117] The same criteria for oral biopsies also apply to esophageal, vulvar, conjunctival, and lacrimal biopsies.

Gastrointestinal GVHD

The diagnosis and monitoring of GVHD in the GI tract require a multidisciplinary approach including the clinician, gastroenterologist, and pathologist. Patients frequently present with GI symptoms including nausea, vomiting, anorexia, and secretory diarrhea. Severe cases can evolve to GI bleeding and protein-losing enteropathy. GI GVHD is a patchy and focal disorder and the primary site of activity does not always correlate with symptoms. Imaging studies are frequently non-specific and show diffuse mucosal

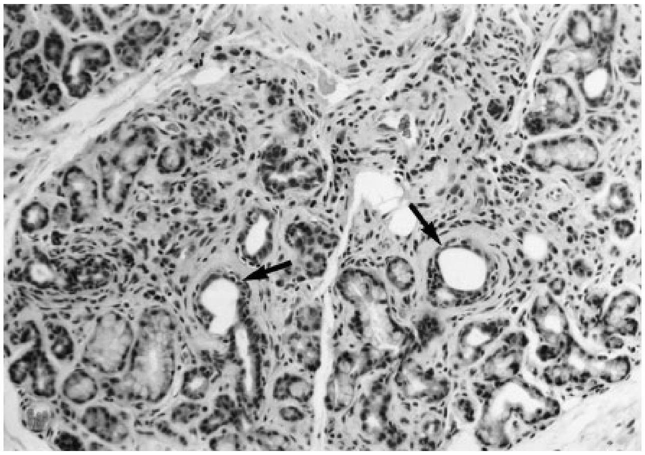

Figure 26.47 Lip biopsy, minor salivary gland. The lymphoplasmacytic inflammatory cells are centered around small ducts. Signs of ductal epithelial cell destruction, irregularity of outline, nuclear stratification and hyperchromatism, and apoptosis (arrows) are similar to GVHD changes in small bile ducts. The glandular interstitium is becoming fibrotic and the acini atrophic, resulting in a sicca syndrome.

edema with effacement of the normal mucosal folds involving the stomach, and entire small and large bowel (Figures 26.49–26.51). Endoscopic analysis provides a visible survey of the entire surface mucosa and facilitates GI biopsies for culture and histologic analysis. The endoscopic appearance of GI GVHD varies from diffuse edema and erythema including friable mucosa to focal erosions, ulcers, and sloughing of the epithelial mucosa. There are multiple studies that show a significant discordance between endoscopy and histology attributed to sampling bias and sensitivity. The gross appearance of GI GVHD usually involves edema of the intestinal wall that is readily apparent to the radiologist who performs imaging tests of the intestine and to the endoscopist who can also see mucosal erythema, friability, and microerosions. However, edema and erythema are not often appreciated by the pathologist, whose specimens are limited to tissue above the muscularis mucosa and dehydrated during tissue processing (Figures 26.49 and 26.50). The endoscopic diagnosis of GVHD is based on findings that the pathologist cannot appreciate [92,118] (Figure 26.51). Likewise, the diagnosis of GVHD by histology is based on microscopic findings and isolated apoptotic cells that are not detected during endoscopy. Multiple studies have reported a lack of visible endoscopic lesions in many cases that were diagnosed as GI GVHD by histology [78]. It is important to emphasize that the endoscopist can visually inspect large areas of GI mucosa and the most severely involved lesions may not be amenable to biopsy. On the other hand, histologic examination is limited to a small tissue biopsy and is therefore affected by sampling bias. Hence the gold standard for GI GVHD may not be histology alone [119,120], but a composite of clinical signs,

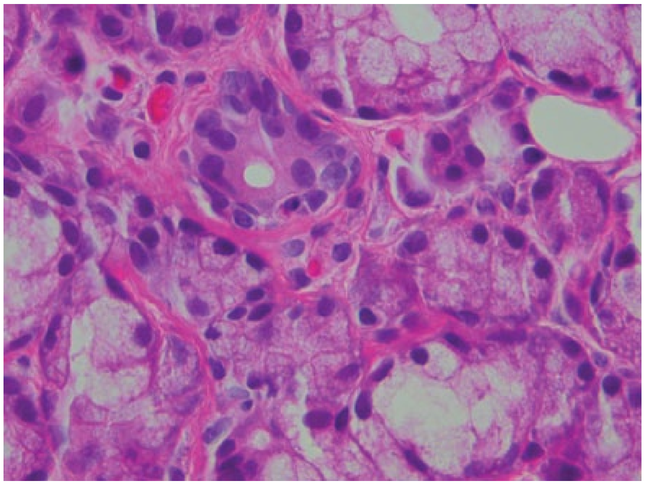

Figure 26.48 GVHD in a salivary gland biopsy from a patient with aplastic anemia day 81 after HCT on with apoptotic cells in the intercalated ducts and architectural distortion with nuclei disarray. (For a color version of this figure, please see the color plate section.)

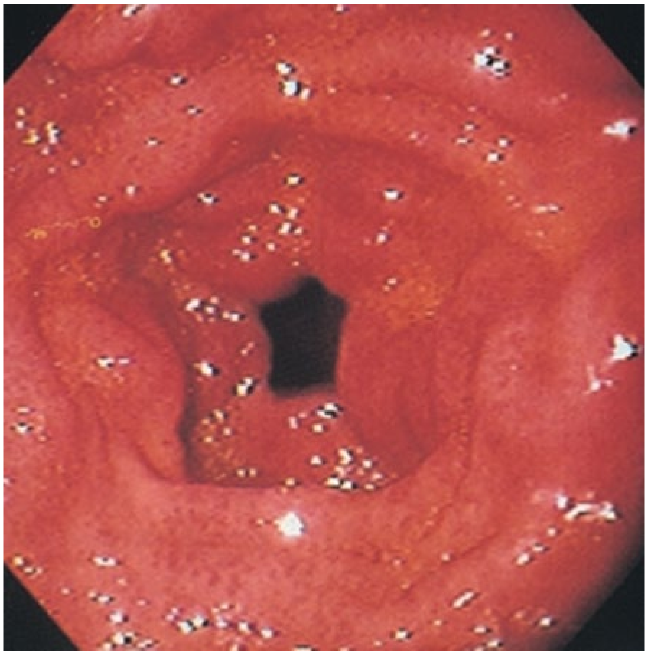

Figure 26.49 Endoscopic appearance of acute GVHD in the stomach, day 32. The pyloric channel is in the center of the picture. The mucosa of the gastric antrum is edematous, reddened, and friable. (For a color version of this figure, please see the color plate section.)

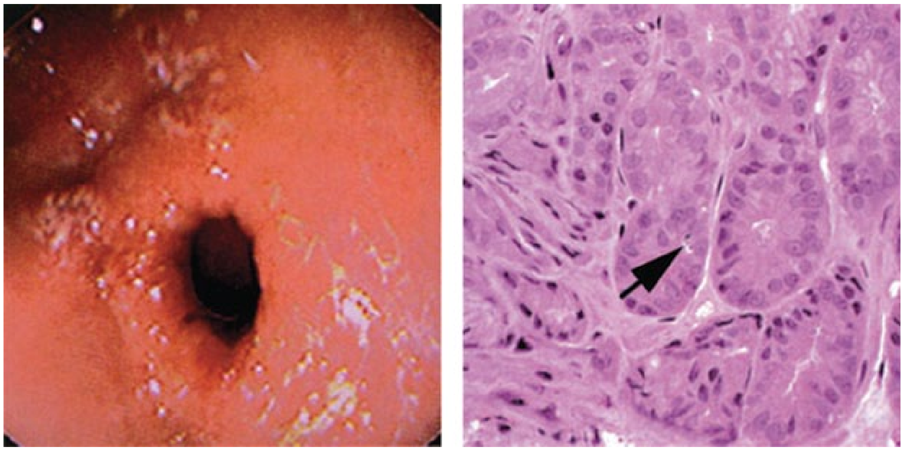

Figure 26.50 Gastric GVHD in which the severe mucosal erythema, edema, and erosion seen endoscopically on the left are more striking that the focal, mild, epithelial cell apoptosis (arrow) in the histological section on the right. Although a lymphocytic infiltrate is absent, apoptosis in multiple crypts is consistent with graft-versus-host activity. Inflammation may have been partially controlled by immunosuppressive therapy. Figure 26.51 Gastric GVHD in which the antral mucosa is endoscopically normal aside from edema (left). With air insufflation through the endoscope the antrum did not distend and there was no motor activity. Biopsy of such a bland area can be diagnostic. In this case, as shown in the photomicrograph on the right, there was epithelial cell apoptosis (arrow) and moderate lymphocytic infiltration diagnostic for GVHD. Source: Ponec et al. 1999 [118]. Reproduced with permission of Elsevier. (For a color version of this figure, please see the color plate section.)

biomarkers, endoscopic appearance, histologic findings, and absence of infection by culture and histology [4,6,78].

The histologic diagnosis of GI GVHD is based on the identification of apoptotic epithelial cells that are usually found in the regenerative or stem-cell areas (i.e. the neck region of the gastric glands, the basal layer of esophagus, and the lower lateral basilar portion of the crypts in the small and large bowel) (Figure 26.27). Severe cases with frequent apoptotic cells and glandular disruption are easily identified with good inter-observer correlation. However, the minimal histologic criteria for GI GVHD have not been established and there is considerable debate on the number and frequency of apoptotic cells required for the diagnosis. There is good intra-observer identification of apoptotic cells but significant discordance on the diagnostic interpretation, especially in mild cases of GI GVHD. In our practice, we usually set a minimal threshold of one apoptotic epithelial cell per tissue fragment for a diagnosis of GI GVHD once other possible etiologies including conditioning, infection, and drug reaction have been eliminated. Individual apoptotic surface epithelial cells are ignored, interpreted as non-specific changes attributed to other etiologies including bowel preparatory regimens.

The location, timing, and frequency of endoscopic biopsies are highly dependent on institutional bias and past experience with complications. Usually patients with gastric GVHD present with nausea and vomiting and those with colonic GVHD present with diarrhea. Some institutions target the endoscopy to the patient's symptoms. However, one study showed that gastric biopsy provided the highest diagnostic yield even when the predominant symptom was diarrhea [120]. The combination of rectal biopsy and gastric biopsy provided the highest diagnostic yield for GVHD [121]. To avoid potential complications associated with upper endoscopic biopsies, a pediatric study advocated the use of the less invasive rectal biopsy alone as an initial survey for GVHD [122]. In general, upper endoscopic biopsies are more difficult to interpret than rectal biopsies because of the disagreement on the minimal diagnostic threshold criteria for apoptosis and the overlap with reactive and inflammatory conditions. There are also differing opinions on whether a biopsy from the duodenum [59], gastric fundus [123], or antrum [120] provides the greatest sensitivity. However, in our experience, GI GVHD is a patchy disorder and can frequently be limited to isolated gastric or colonic involvement, necessitating additional endoscopy if a more limited study is negative.

Spectrum of gastrointestinal GVHD

The sequence of damage in gut GVHD has been conceptualized into a four-tier grading system that is a modification of the original Lerner histologic grading schema [91]:

1. *Grade I:* Individual cell necrosis in basal and lateral crypts, with sparse lymphocytic infiltrate (Figure 26.50–26.53). The minimal criterion is a single or rare apoptotic crypt cell, referred to as an exploding crypt cell. These alterations may involve only a few scattered crypts and can be missed unless the specimen contains properly oriented biopsies with multiple serial sections. In the grade I lesion, the exploding crypt cell may not have an accompanying lymphocytic infiltrate. Histologic grade I does not mean that the entire gut has the same grade; it is not uncommon for gastric and/or rectal biopsy histology to underestimate the severity of GVHD in the midgut, particularly the ileum.
2. *Grade II:* An apoptotic crypt abscess involves at least 1/3 of the glandular circumference. The dilated crypt is lined by thin epithelium devoid of mucin, and infiltrated by lymphocytes. The crypt abscesses contain apoptotic debris. A scattering of lymphocytes, neutrophils, and eosinophils may be present in the interstitium, crypt walls, and crypt abscesses. They may be present in considerable numbers, especially after withdrawal of immunosuppression in a fully engrafted recipient (Figure 26.54; see also Figures 26.27 and 26.53).
3. *Grade III:* Crypt loss resulting in stretches of mucosa devoid of crypts with some focal ulceration (Figure 26.55).
4. *Grade IV:* Mucosal denudation. Widespread ulceration with loss of the surface epithelium and crypts (Figure 26.56; see also Figures 26.57 and 26.58). This results in an empty lamina propria devoid of surface epithelium and crypts. There may be granulation tissue and scattered areas of hemorrhage. In grades II–IV, the dilated small vessels in the lamina propria are lined by reactive-appearing endothelium and infiltrated by mixed cell populations. Multiple representative samples should be obtained and correlated with the endoscopic locations since areas of mucosal destruction and ulceration can be adjacent to large stretches of regenerative mucosa with little or no apoptotic activity.

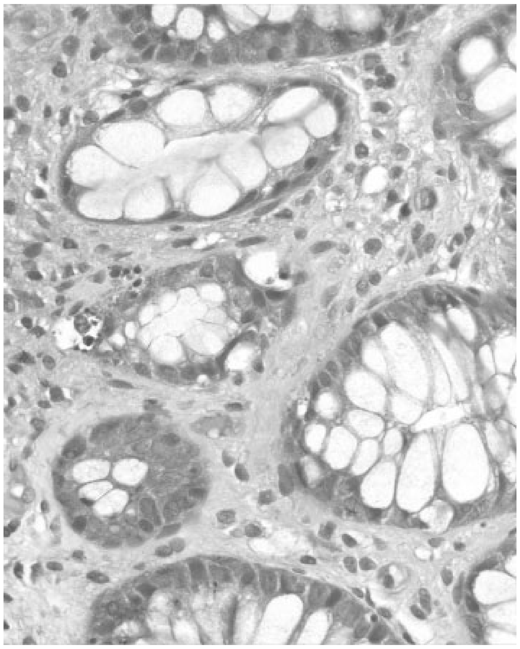

Figure 26.52 Colonic GVHD, grade I. A single crypt displays individual epithelial cell apoptosis (“exploding crypt cell”).

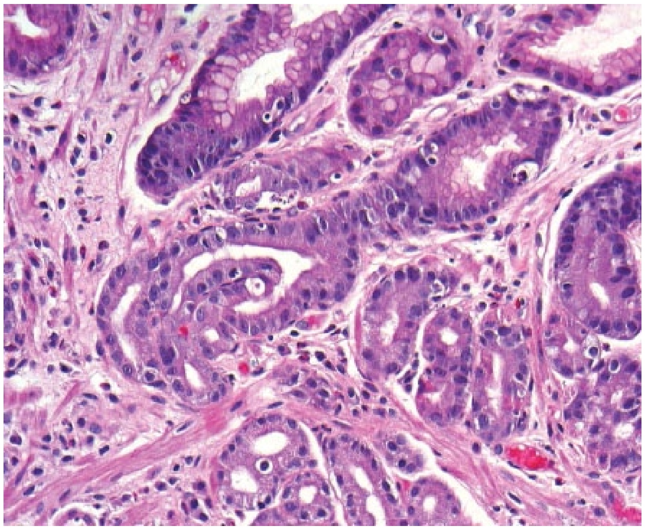

Figure 26.53 Gastric GVHD with architectural disarray and edematous antral mucosa. There are numerous intraepithelial lymphocytes infiltrating glands which also demonstrate reactive atypia. Apoptosis is widespread along with segmental disruption of the glands. (For a color version of this figure, please see the color plate section.)

Although the grading system is a useful descriptor, it is not intended to reflect severity since all four grades may be associated with extensive involvement and severe symptoms. Grade I covers a wide spectrum of damage, ranging from rare individual exploding crypt cells to widespread apoptosis, both single and confluent within a single crypt (Figure 26.53). In practice, identifying the minimal diagnostic threshold for grade I can require analyzing many serial sections. Focally enhanced gastritis, a focal mixed lympho-histiocytic infiltrate with or without neutrophils surrounding a small group of glands without apoptosis, can be associated with

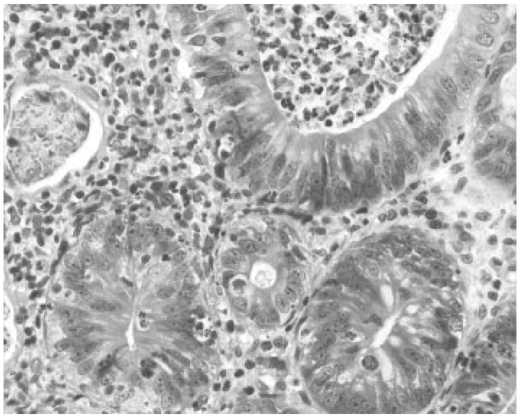

Figure 26.54 Colonic GVHD, grade II. Destruction of crypts with formation of crypt abscesses containing apoptotic debris.

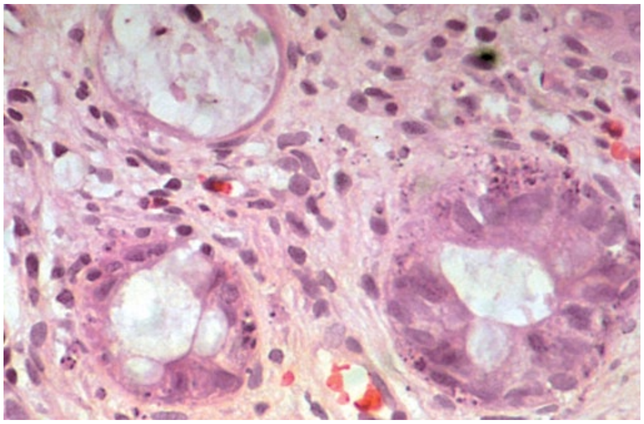

Figure 26.55 Rectal biopsy with GVHD, day 53. Three mucosal crypts display varying degrees of damage. The crypt on the right shows many apoptotic cells. More extensive cell damage is present in the crypt on the lower left. The upper crypt has lost all enterocytes. Note infiltrating lymphocytes in the lower left crypt associated with nuclear debris characteristic of apoptosis. Source: reproduced with permission of Dr. Robert C. Hackman. (For a color version of this figure, please see the color plate section.)

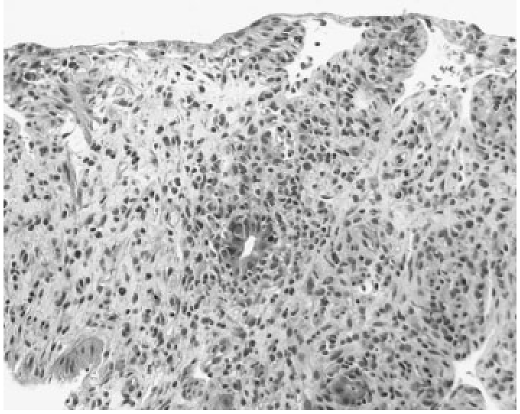

Figure 26.56 Grade IV GVHD in a day 48 duodenal biopsy. Mucosal ulceration with loss of villous epithelium and subtotal destruction of crypts. The features that indicate the cause as GVHD are the two small remaining degenerative crypts showing apoptosis and infiltration by lymphocytes and eosinophils. Concurrent biopsies from the stomach and colon had less severe damage: focal grade III and grade II changes, respectively.

GVHD but, by itself, is non-specific [124]. The cumulative damage in grade II and III GVHD is typically widespread, whereas in grade IV there may be no crypts left to demonstrate the apoptotic destruction of the earlier grades and is therefore difficult to monitor continued activity (Figure 26.56). It is important to realize that all four grades may occur in different biopsies from concurrent samples. In contrast to the colon and small bowel, the stomach rarely develops diffuse grade IV changes. Grade IV GI GVHD is slow to heal and often refractory, even with secondary immunosuppressive treatment or aggressive surgical management of obstruction (Figure 26.57). The inability to re-epithelialize, even with prolonged secondary treatment for gut GVHD, may result from a loss of the mucosal stem cells (Figure 26.58). In a recent study, Takashima et al. demonstrated that stimulation of the ISCs with a Wnt agonist (R-Spo-1) protected the cells against GVHD damage and enhanced restoration of the injured intestinal epithelium [63]. Since GVHD is a patchy disorder, serial colonoscopic biopsies obtained to monitor therapeutic response and epithelial regeneration frequently show discordant results attributed to various stages or activity and repair. Rarely, refractory gut GVHD may develop collagenous deposits within the lamina propria, submucosa, and serosa or a segmental intestinal stenosis with ulceration and fibrosis confined to the mucosa and submucosa (Figures 26.57 and 26.59).

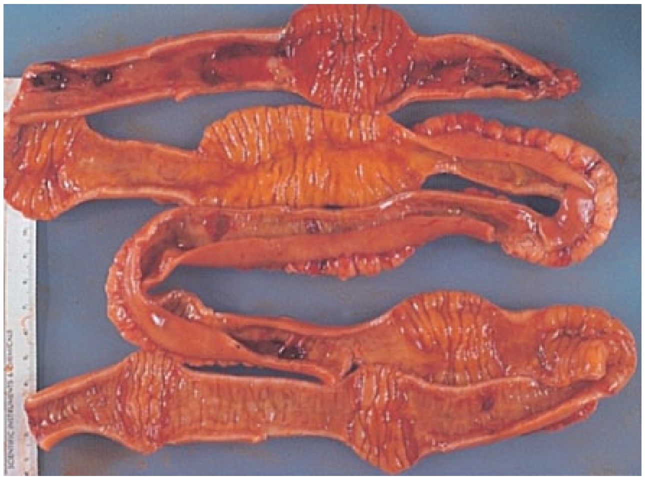

Figure 26.57 Surgical resection of severe long-standing intestinal GVHD, day 207. Scarred, ulcerated mucosa alternates with dilated areas of mucosal regeneration. The ulcerated portions demonstrate complete loss of epithelium and severe submucosal fibrosis. There is very high risk of invasive fungal or bacterial infection. Some patients have responded well to intestinal resection for localized GVHD. (For a color version of this figure, please see the color plate section.)

Differential diagnosis

One reason why there is a lack of consensus on the minimal diagnostic criterion for gut GVHD is because low levels of apoptosis are not specific to GI GVHD and can occur with various medications, including non-steroidal inflammatory inhibitors, mycophenolate mofetil (MMF), proton pump inhibitors [53,125], and with some infectious and/or reactive causes such as cryptosporidiosis and phosphate enemas [119]. In general, reactive gastropathy does not produce epithelial apoptosis. The tissue biopsies for GVHD evaluation must come from flat normal-appearing mucosa since

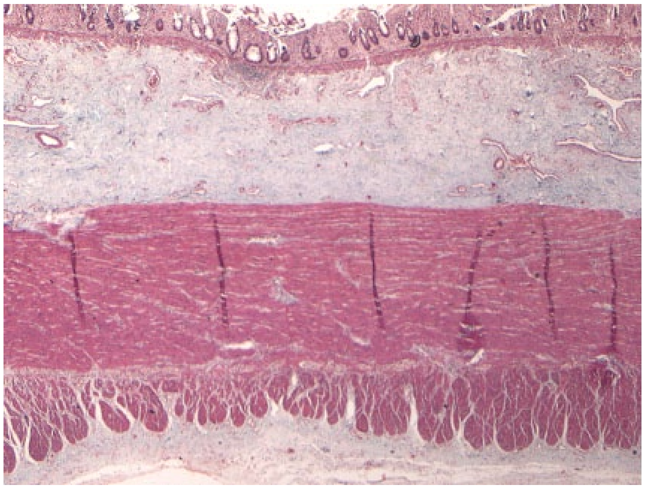

Figure 26.59 Collagenous colitis with long-standing refractory extensive chronic GVHD. The thickened bowel has extensive deposition of collagen in the submucosa, serosa as well the lamina propria. (For a color version of this figure, please see the color plate section.)

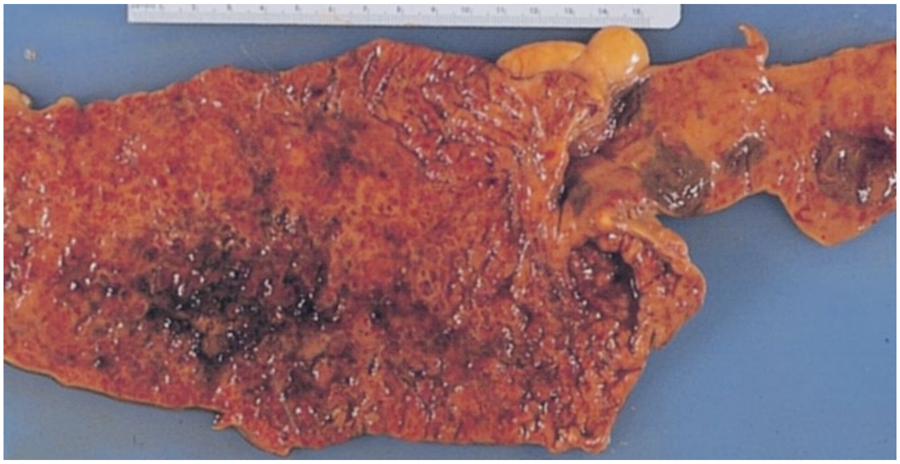

Figure 26.58 Severe GVHD of ileum and cecum, day 80. The mucosal lining and folds are replaced by a friable, beefy red, diffusely ulcerated lamina propria. The numerous exposed capillaries ooze blood and serum, a major cause of morbidity from intestinal GVHD. The endothelial cells and fibroblasts within the lamina propria are often infected with CMV, as was true in this patient. (For a color version of this figure, please see the color plate section.)

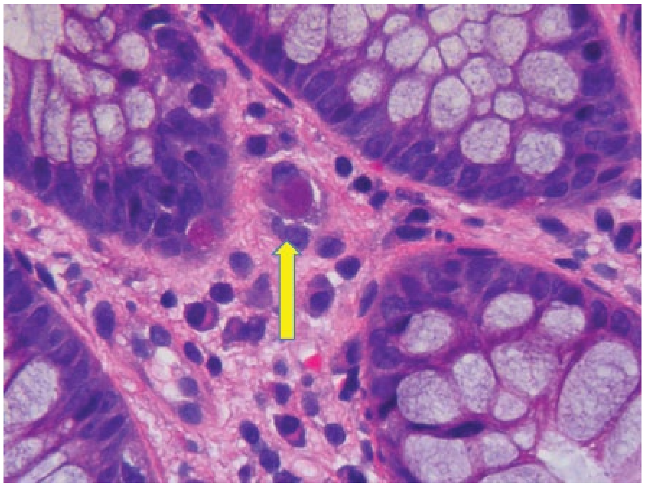

Figure 26.60 CMV infection in a patient with T-cell prolymphocytic leukemia from day 516 after HCT with chronic diarrhea. The yellow arrow indicates the classic large eosinophilic inclusion in a stromal cell. (For a color version of this figure, please see the color plate section.)

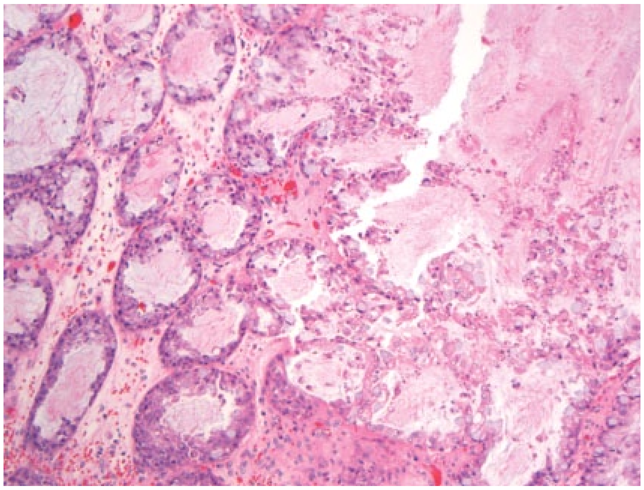

Figure 26.61 Fatal pseudomembranous colitis. An acute abdomen developed 15 days post-transplant. The degenerative colonic crypts were covered with a cap of mucin admixed with sloughed cellular debris containing large colonies of bacteria consistent with *Clostridium* sp. (For a color version of this figure, please see the color plate section.)

hyperplastic polyps and adenomas frequently have scattered apoptotic epithelial cells due to the increased epithelial proliferation. The differential diagnosis of grade II–IV changes includes cytomegalovirus (CMV) enteritis that produces a range of changes from shallow circular ulcers to an inflammatory pseudotumor mass involving multiple layers of the gut (Figure 26.58). The viral inclusions typically involve the endothelium but may also affect stromal cells and gut epithelium (Figure 26.60). There is a long-standing controversy as to whether the presence of CMV enteritis (a well-known cause of apoptosis in gut biopsies) precludes a diagnosis of GVHD [119]. Studies have addressed this issue using IHC and in situ hybridization for CMV and caspase 3 IHC for GVHD [76,126]. In CMV enteritis, apoptosis was largely confined to the cells with immunoreactive CMV antigens, whereas apoptotic cells were much more numerous in GVHD. These studies concur with the NIH chronic GVHD consensus [53] that multiple apoptotic crypt cells remote from CMV infected cells indicate the co-presence of GVHD. Antibiotic-related pseudomembranous colitis is related to the toxin produced within the colonic lumen by *Clostridium* species, especially *Clostridium difficile*. If severe, it can produce ischemic changes with apoptosis. Pseudomembranous colitis is distinguished from GVHD by the characteristic superficial pseudomembranous cap of neutrophils, mucin, and necrotic cells with or without bacterial rods and by a positive assay for the *C. difficile* toxin (Figure 26.61).

The immunosuppressive drug MMF can produce colitis and even upper gut damage [127,128] with focal ulcerations, marked apoptosis, and intense acute and chronic inflammation. In practice, the distinction of MMF colitis from GVHD is often established by improvement in bloody diarrhea after drug withdrawal [127]. There are insufficient data on whether MMF often produces lesions in the upper gut. Immune checkpoint blockade with antibodies that target cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) and the programmed cell death protein 1 pathway (PD-1/PD-L1) provides a novel way to augment antitumor immunity by effector T-cells. Immune related adverse events arise triggering inflammatory conditions in the skin and colon that mimic GVHD, with frequent apoptotic epithelial cells, ulceration, and loss of colonic mucosa [129,130,131]. However, a dose escalation trial using ipilimumab to treat relapsed malignancy after HCT demonstrated induction of a graft-versus-tumor response without stimulating significant GVHD [132].

In 2011, Herrera [133] described a newly defined syndrome cord colitis (CCS) consisting of a colitis confined to cord blood recipients with late-onset secretory diarrhea, absence of GVHD or detectable infections with mucosal features of chronicity [134] and some cases with multicentric granulomatous inflammation that was responsive to antibiotics but not immunosupppression. Two subsequent studies disproved the CCS as a distinct entity since the histologic features of chronic mucosal damage or granulomas were not restricted to cord blood recipients [135,136].

Esophageal GVHD

Like most squamous epithelia, that of the esophagus may be involved with GVHD. The diagnosis of acute GVHD presents considerable diagnostic difficulty since a variety of conditions, including acid peptic reflux and infections, can produce mucosal damage. Unless there is a combination of lichenoid interface changes with apoptosis along the basilar portion of the mucosa, the diagnosis of esophageal GVHD should be made with some qualification. Accurate diagnosis requires special stains and often IHC studies for microorganisms. Bacterial, viral, and fungal cultures should be obtained endoscopically from lesions suggestive of infection (Figures 26.62 and 26.63).

Autologous GVHD

Autologous GVHD was first described by Hood et al. as an autoimmune syndrome similar to acute GVHD that occurred in patients receiving an autologous stem-cell transplant [137]. Autologous GVHD or autoaggression syndrome is frequently a self-limited and mild disorder that responds well to therapy; nearly all patients show durable responses to one or two courses of prednisone. Traditionally, autologous GVHD is most commonly seen in the skin, although one study reported that 13% of autografted recipients developed a GI syndrome that was both clinically and histologically indistinguishable from acute GVHD occurring in allogeneic recipients [138]

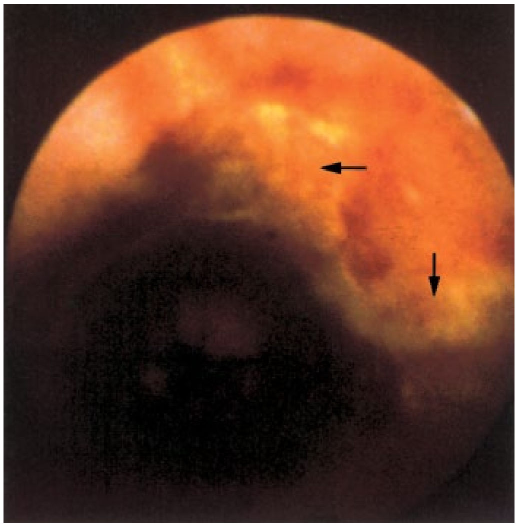

Figure 26.62 Endoscopic appearance of CMV esophagitis, day 61. A large, shallow ulcer with serpiginous, reddened borders is seen in the distal esophagus. The ulcer base (arrows) has a yellow, reticulated appearance. (For a color version of this figure, please see the color plate section.)

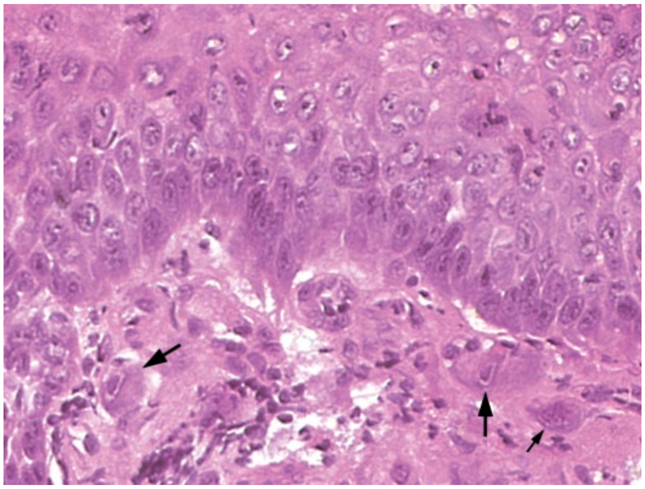

Figure 26.63 Esophageal biopsy showing CMV infection, day 61. Beneath the epithelium are two cytomegalic cells (large arrows), each containing a single, large, oval intranuclear inclusion surrounded by a clear halo (Cowdry type A). A third cell (small arrow) is probably also infected but is morphologically non-diagnostic. It would presumably be positive by immunocytochemistry and in situ hybridization techniques. Studies of cell morphology and also viral DNA and antigen expression indicate that the esophageal squamous epithelium is never infected with CMV. (For a color version of this figure, please see the color plate section.)

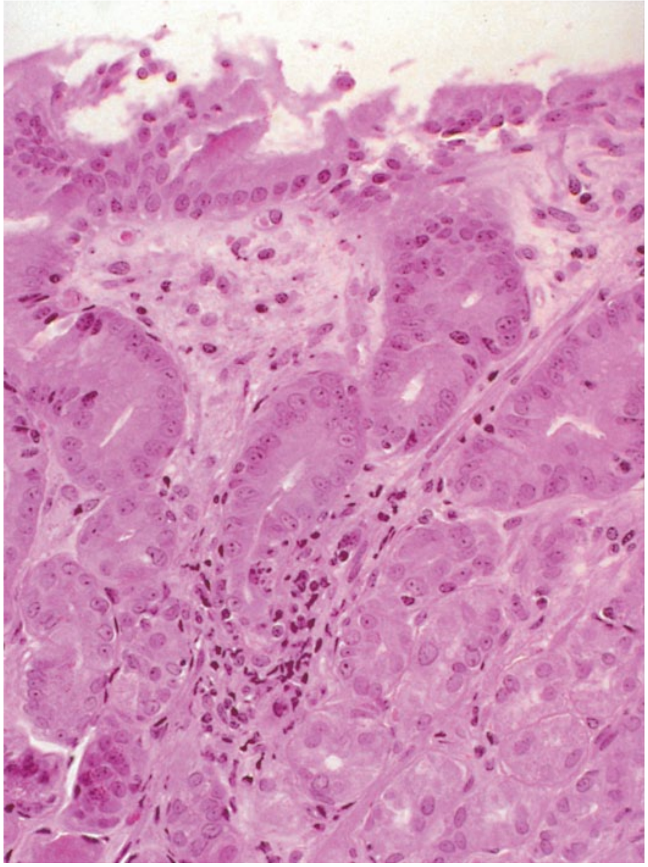

Figure 26.64 Autologous gastric GVHD or lymphocytic gastritis. The focal mononuclear inflammatory cell infiltration of the lamina propria and mucosal crypt associated with crypt epithelial cell apoptosis is histologically indistinguishable from GVHD in an allograft recipient. This inflammation may develop after autologous or syngeneic BMT if tolerance to self-MHC antigens is not re-established and autoreactive cells are allowed to persist. (For a color version of this figure, please see the color plate section.)

(Figure 26.64). Autologous transplantation is an effective therapy for treating plasma cell myeloma, although relapse remains a major problem. In a recent study, Lazarus et al. reported a cohort of myeloma patients that spontaneously developed autologous GVHD predominantly limited to the GI tract within 1 month after autologous transplant. These patients received high-dose melphalan conditioning that may have contributed to the onset of autologous GVHD [139]. Many clinical studies have been performed to determine whether induced autologous GVHD may also promote an autologous graft-versus-tumor response, but there is as yet no convincing evidence for this effect. The genesis of autologous GVHD is thought to be related to both compromised thymic function resulting in failure to delete autoreactive T cells and the elimination of regulatory T cells in the hematopoietic autograft [140].

Hepatic GVHD

The liver is a major target of allogeneic GVHD [26], and occasionally also autologous GVHD [141]. With improvements in clinical management, the overall prevalence of severe grade III–IV hepatic GVHD has markedly decreased, from 11.9% in 1993–1997 to 2.1% in 2003–2007 [7]. Liver involvement is heralded by a gradual rise in bilirubin and alkaline phosphatase and aminotransferase enzymes. It typically follows acute cutaneous or intestinal GVHD; but can present as the sole manifestation of GVHD. The initial elevation in liver tests is likely mediated by cytokine induction of the Fas/Fas ligand system leading to bystander death of hepatocytes. In both the experimental and clinical settings, histopathologic and ultrastructural studies demonstrate that the small interlobular bile ducts are the preferential targets of the alloimmune reaction (Figure 26.65; see also Figure 26.66). The characteristic dysmorphic interlobular bile ducts of GVHD have a withered, shrunken appearance with a collapsed lumen, vacuolated cytoplasm, and irregular outlines. Individual or groups of epithelial cells are flattened and often missing

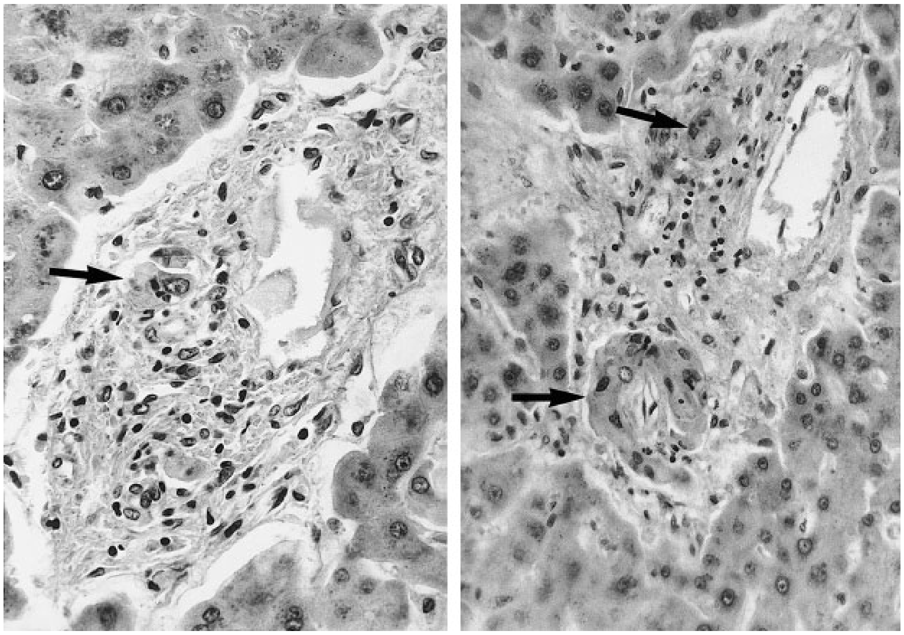

Figure 26.65 Hepatic GVHD, day 53. Despite the minimal inflammation within the portal space, the bile ducts (arrow) are reduced to degenerative cytoplasmic masses with a few remaining hyperchromatic nuclei.

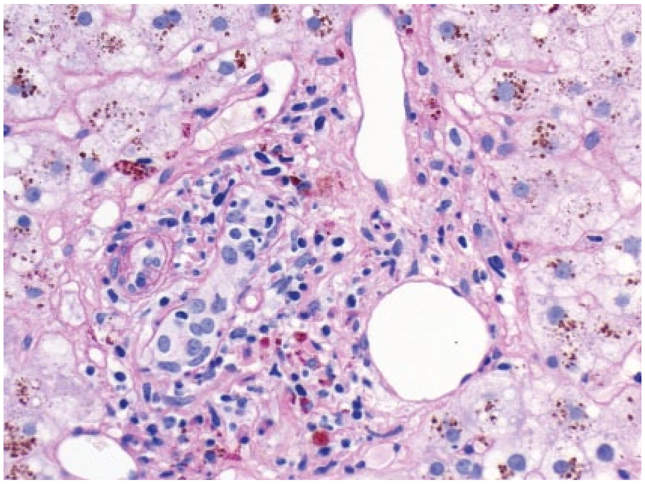

Figure 26.66 Hepatic GVHD. The PAS-stained section highlights a damaged interlobular bile duct that is infiltrated by lymphocytes. The nuclei vary in size and are irregularly arranged. The syncytium-like segment reflects nuclear loss. (For a color version of this figure, please see the color plate section.)

nuclei, creating segments of anucleate eosinophilic cytoplasmic syncytia. Remaining nuclei display atypical features with anisonucleosis, hyperchromasia, and dyspolarity. Lymphocytic ductitis is frequently present in the damaged portions of the biliary epithelium but apoptosis of bile duct epithelium is infrequent.

The histologic interpretation is directly affected by the quality, size, and timing of the sample. Thin core needle biopsies may be difficult to interpret owing to limited sampling of portal areas or crush artifact. The timing of the liver biopsy influences the histologic finding. When liver biopsies to diagnose GVHD are obtained soon after the onset of liver dysfunction, the characteristic bile duct changes may be absent or affect a minority of portal spaces. In a study that included serial liver biopsies, the initial biopsies taken at the onset of symptoms failed to show the characteristic bile duct damage, whereas follow-up biopsies taken 10 days later showed histologic signs of hepatic GVHD [142]. The amount and extent of the inflammatory component in liver GVHD are dependent on the degree of immunosuppressive treatment. The portal infiltrate is typically lymphocytic but may include a minor component of loosely scattered neutrophils, eosinophils, monocytes, and plasma cells. In a typical biopsy from a patient on therapeutic levels of immunosuppressive agents, inflammation is typically mild to scant, even with extensive bile duct damage (Figure 26.65).

Hepatic GVHD is no longer classified as acute or chronic [53,143]. The histology is largely unrelated to the period when the GVHD arose but is rather a reflection of the duration of active liver GVHD, the anti-inflammatory effects of immunosuppression, and the anticholestatic effect of ursodeoxycholic acid. A late clinical presentation of isolated liver GVHD with an acute hepatitic onset may develop as the solitary manifestation of GVHD, following tapering or cessation of immunosuppressive therapy or after donor lymphocyte infusion. The "hepatic onset of GVHD" is characterized by marked elevation of aminotransferase enzymes with prominent periportal inflammation that may include plasma cells and a lobular hepatitic component with abundant necroinflammatory activity (pyknotic shrunken hepatocytes, acidophilic bodies) [144]. In some cases, the bile duct damage may be less conspicuous owing to the marked inflammation and hepatocyte necrosis related to the accompanying cytokine storm (Figures 26.67 and 26.68).

The histologic threshold for diagnosing liver GVHD rests on qualitative rather than quantitative changes, given the enormous variability in the size and quality of liver biopsies. Special stains, including trichrome, periodic acid–Schiff (PAS)/diastase, reticulin, iron and immunohistochemical stains for cytokeratin 19 or 7, should be included in the workup. With prolonged liver GVHD, bile duct destruction is best appreciated by stains other than H&E (e.g. cytokeratin 7 or 19, trichrome, or PAS) (Figure 26.66). Hepatic

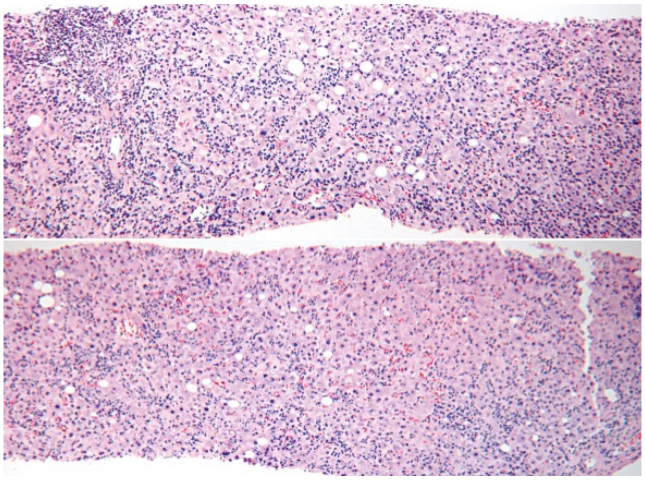

Figure 26.67 Acute hepatitic onset of GVHD at 10 months post-transplant. Three months after tapering off immunosuppression, the aminotransferases rose to 2000 u and alkaline phosphatase three times normal with normal bilirubin. This biopsy 1 was performed 26 days from the onset and shows an extensive lobular hepatitis with intense lymphocytic inflammation of sinusoids and portal spaces and hepatocellular necrosis. (For a color version of this figure, please see the color plate section.)

GVHD produces a variety of cholestatic changes, including canalicular bile plugs, hepatocyte ballooning, and dropout of hepatocytes in the perivenular zone along with a scattering of lymphocytes and collections of pigment-laden macrophages (Figure 26.68). Rarely, pseudo ground-glass PAS diastase-resistant hepatocytes develop from accumulation of abnormal glycogen [145,146]. Frequently, there is some degree of ductular reaction, a proliferation of small ductules along the periphery of the portal space that is common in inflammatory liver diseases. In addition to being a reparative response to duct injury, the proliferated ductules also appear to become a secondary target of liver GVHD because the destructive lymphocytic ductitis and cytologic changes in the ductules are similar to those in the damaged interlobular bile ducts. By analogy, in the immune mediated cholangiopathy of primary biliary cirrhosis, proliferated ductules and mature cholangiocytes displaying aberrant expression of I-CAM-1 were found in close association with lymphocytes expressing LFA-1, suggesting a similar lymphocytic targeting of the bile ductile epithelial cells [147]. A particularly striking form of cholangiolar cholestasis with dilated periportal bile-filled ductules occurs in patients with concomitant intestinal GVHD (Figure 26.69; see also Figure 26.70). This resembles cholangitis lenta associated with septicemia and results from the coexisting influence of gut GVHD, showering the liver with endotoxin which,

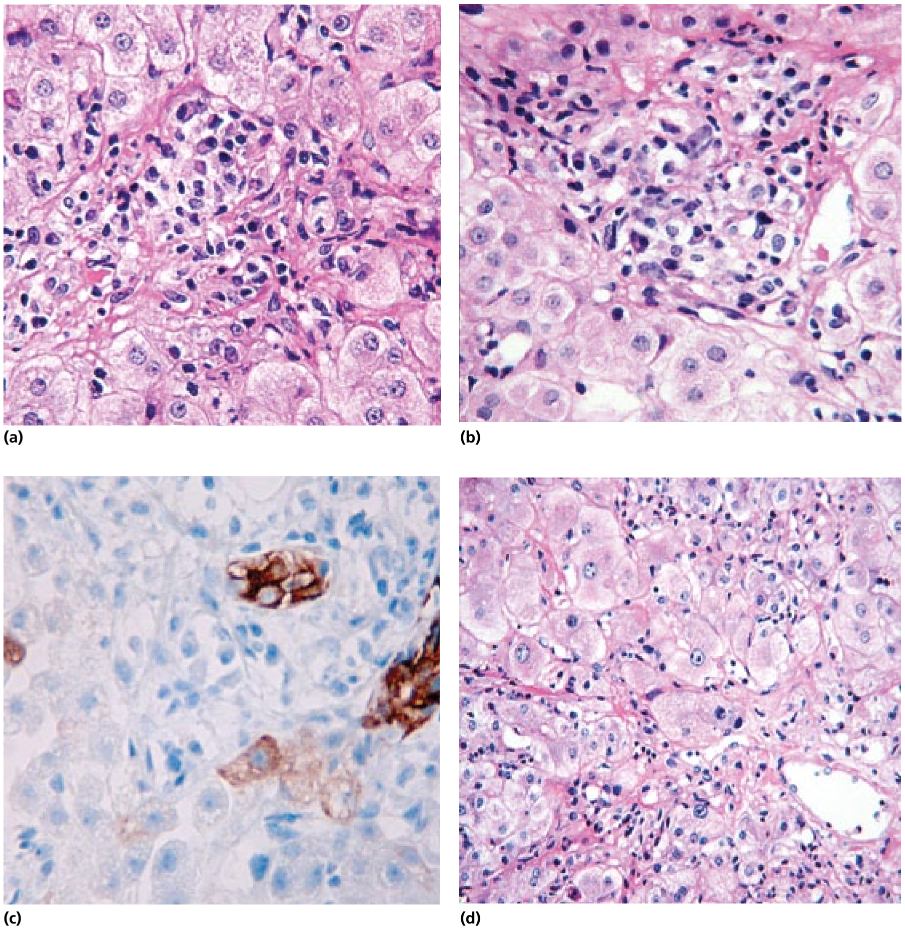

Figure 26.68 This biopsy 2 was done 1 month later (see Figure 26.67) when the total bilirubin was 30mg/dL. Images (a) and (b) show a lymphoplasmacytic portal infiltrate which obscures the damaged interlobular bile ducts. In (c), immunostaining with cytokeratin 7 demonstrates that damaged bile ducts are still present. In (d), there is perivenular (zone 3) cholestasis. Hepatocytes show ballooning, and there is focal dropout associated with a patchy lymphocytic infiltrate. The patient made a full recovery after immunosuppressive treatment for GVHD was initiated. (For a color version of this figure, please see the color plate section.)

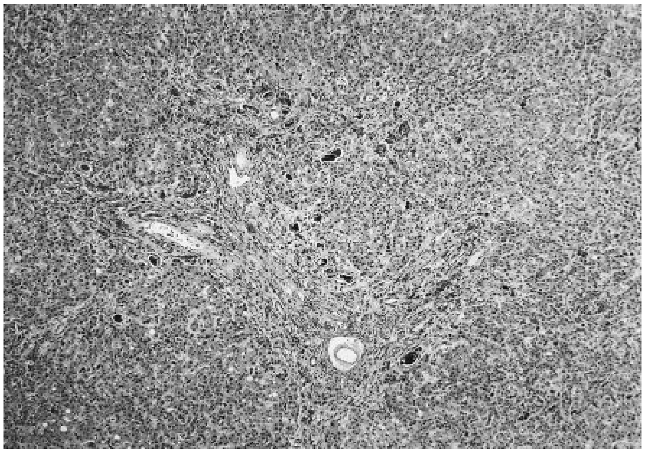

Figure 26.69 Hepatic GVHD, day 56. There is pronounced hepatocellular and cholangiolar cholestasis with portal-to-portal bridging and parenchymal collapse. Cholangioles have proliferated along the limiting plate.

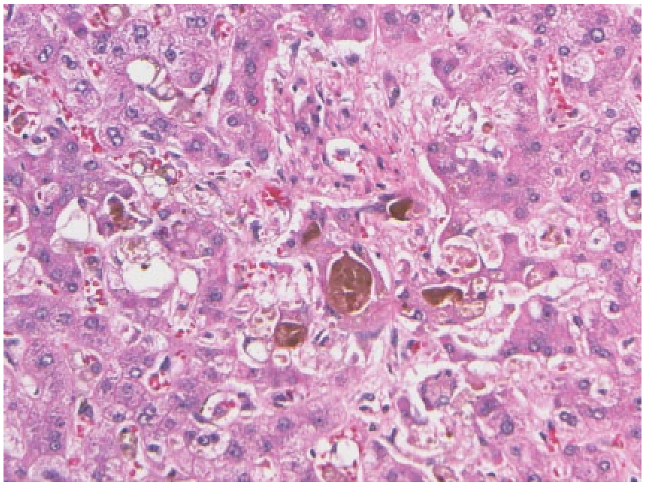

Figure 26.70 Hepatic GVHD with severe cholangitis lenta-like cholangiolar hepatocellular cholestasis. The interlobular bile duct is no longer recognizable. A ductular reaction with large bile-filled cholangioles lies along the periphery of the enlarged irregular portal space. The adjacent hepatocyte cords display marked unrest, disarray, and cytoplasmic ballooning. (For a color version of this figure, please see the color plate section.)

in turn, stimulates TNF-α and Il-6, a promoter of bile ductule proliferation and cholestasis [148]. A consequence of ductular reaction is the development of stellate fibrosis, periportal fibrous septae which extend out into the liver acinus, and rarely bridging fibrosis [26] (Figure 26.69). However, even in prolonged refractory liver GVHD with loss of bile ducts, cirrhosis rarely occurs. The few anecdotal case reports of cirrhosis related to GVHD were tainted by inadequate immunosuppression or the previous high prevalence of hepatitis C virus infection [26]. Nearly all cirrhosis developing in allogeneic recipients after 10 years post-HCT is attributed to hepatitis C virus (HCV) infection [149].

Despite the similarities of liver GVHD to rejection of orthotopic liver allografts, there have been no studies of human liver GVHD showing that the bile duct loss is caused by ischemia related to the loss of peribiliary capillaries or obliterative arteriopathy, as has been described in rejection [150].

Differential diagnosis

The timing, profile, and rate of rise of liver test abnormalities provide good indicators as to the likely diagnostic possibilities (see Chapter 94). The histologic differential diagnosis of liver GVHD includes drug liver injury, nodular regeneration, fatty liver disorder, infection, and malignancy, including PTLD. Sinusoidal obstruction syndrome may overlap with GVHD developing later, but it has different histologic features from GVHD. Most of the candidate antimicrobial drugs for causing liver injury do not produce the typical clinical or histologic patterns seen with GVHD. In one study, the frequently used antifungal agent voriconazole produced mild reversible enzyme elevations in 34% of treated patients [151]. In contrast, trimethoprim/sulfamethoxazole can produce prolonged cholestasis. If the clinical situation permits, it is prudent to discontinue the candidate hepatotoxic drug rather than trying to exclude it as a cause by histology. A common finding in patients biopsied after HCT is marked hepatic iron overload within both hepatocytes and Kupffer cells. Although this has been associated with elevated aminotransferases that could be confused with GVHD [26,152], this association has been challenged because although high blood iron measurements per se may be a cofactor in liver disorders, they are rarely the sole cause of serious liver disorders [153]. The iron overload may be multifactorial: early post-transplant it may result from prior multiple transfusions, but later on it is more often the consequence of anemia of chronic disease leading to increased intestinal iron transport coupled with retention of iron in the liver [154]. Infections, especially viral, are an important diagnostic consideration because failure to treat them can lead to liver failure (Chapter 94). CMV should not be considered in the diagnosis of severe hepatitis or jaundice since it results in mild anicteric hepatitis [155] whose principal histologic findings in immunosuppressed patients are microabscesses that contain some neutrophils. However, in a study of CMV in orthotopic liver allografts, the positive predictive value of the occurrence of a microabscess to predict CMV infection in the liver was very low (19%) [156]. The life-threatening adenovirus and herpes group of viral infections that have declined markedly in frequency are discussed in the Infection section below. Surprisingly, in a study of severe hepatocellular injury [aspartate aminotransferase (AST) >1500 U/L] in 6225 HCT recipients, adenoviral infections were not found among the causes [30]. If the portal spaces are greatly expanded by an infiltrate rich in plasma cells, the differential diagnosis and workup should include PTLD (Figure 26.23) (see Chapter 104), the hepatitic onset of GVHD [144], and, rarely, autoimmune hepatitis [26]. The development of positive tests and/or immunohistologic stains for hepatitis B virus (HBV) and HBC does not exclude the coexistence of GVHD. It may be difficult to distinguish bile duct changes in cases of severe reactivation of viral hepatitis B or C from prolonged GVHD with a ductular reaction. We have observed a handful of cases of fibrosing cholestatic hepatitis (FCH) occurring in patients with chronic HBV and HCV [157] (Figure 26.71). In the presence of the characteristic FCH findings of serpiginous bridging fibrosis with marked ductular proliferation, it is not possible to make a morphologic distinction of the viral-induced changes from concomitant GVHD.

The use of the liver biopsy in monitoring the therapeutic response and prognosis of patients with GVHD should utilize a clinicopathologic approach. Biopsies used to evaluate GVHD should indicate whether the histologic changes show progression in comparison with earlier biopsies and indicate how widespread and complete the significant biliary damage or destruction from GVHD is. When viewed as a single picture in time, the pathologist may not be able to

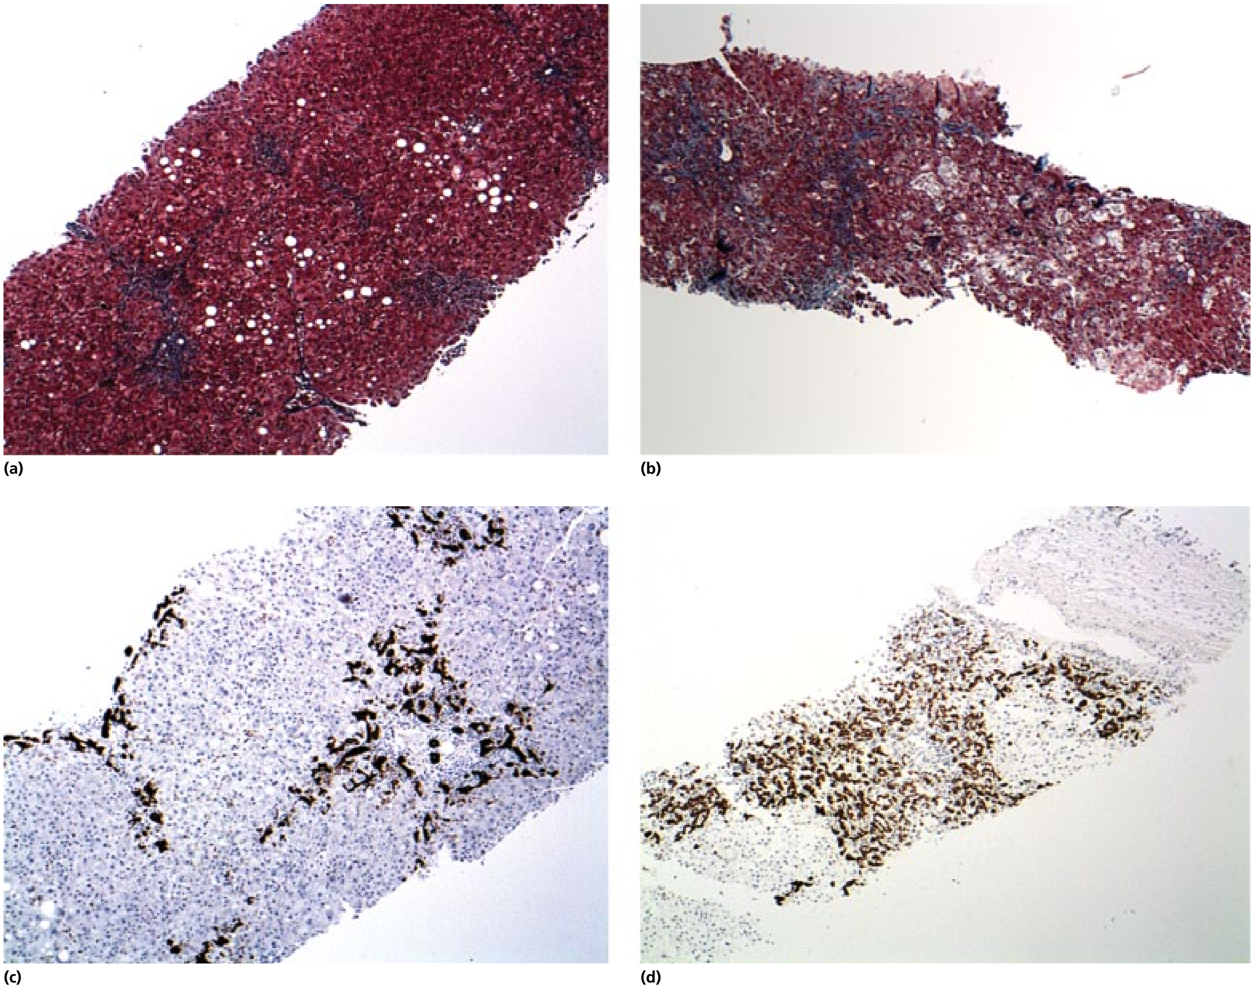

Figure 26.71 Rapidly evolving fibrosing cholestatic hepatitis C. Donor was positive for hepatitis C. Liver biopsies from day 70 [(a) and (c)] and day 88 [(b) and (d)] showing expanding portal fibrosis, hepatocyte necrosis and dropout, and marked bile ductule proliferation seen with cytokeratin 19 IHC [(c) and (d)]. (For a color version of this figure, please see the color plate section.)

determine if the process is inactive or improving since it may take months for the damaged biliary system to recover. Although there is no validated histologic grading system for liver GVHD, evidence-based observations of protracted GVHD indicate that time to recovery from jaundice is proportional to the extent of bile duct destruction.

Pulmonary complications

Pulmonary complications continue to develop in HCT patients and are most frequent in those receiving allogeneic stem cells. In addition to the major role of infection, other mechanisms of injury may include drug toxicity, irradiation damage, GVHD, and cytokine storm. The resulting histologic alterations are often non-specific and may include diffuse alveolar damage, alveolar hemorrhage [158], interstitial and alveolar inflammation, alveolar proteinosis, and pulmonary venous occlusion [159,160] (Figure 26.72). Several of these may coexist in the same patient and interact to cause significant tissue damage and symptoms. Diagnostic evaluation by the pathologist is closely coordinated with the clinical care team. Consideration is given to the underlying major disease and its treatment, possible exposure to infection or toxic damage, prior pulmonary complications, the pre-transplant conditioning regimen,

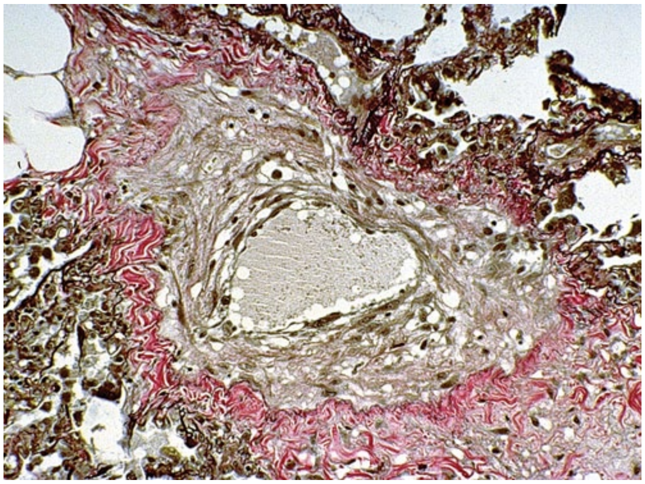

Figure 26.72 Pulmonary veno-occlusive disease (VOD) in a lung biopsy from a patient with pulmonary hypertension 48 days after second allogeneic BMT for acute lymphoblastic leukemia. Loose intimal fibrosis partially occludes the interlobular vein. This complication probably results from chemotherapy and may be more frequent than previously suspected. (Verhoeff–van Gieson elastin stain.) (For a color version of this figure, please see the color plate section.)

the post-transplant interval, the degree of immunosuppression, whether GVHD is present, the results of surveillance cultures and molecular tests for systemic infection, the evolution of signs and symptoms, and the results of imaging studies in addition to pulmonary function tests.

Typically, the first involvement for the pathologist is the immediate analysis of BAL cytospin preparations for possible infection (see the Infection section below) or malignancy. Either negative or positive findings for these two complications will often allow clinicians to focus and thereby simplify therapy. Because the diagnostic yield for BALs is low, tissue is often needed to analyze histological patterns and again carry out detailed morphological, microbiological, and molecular studies for infection. Transbronchial biopsies can usually be obtained safely and may fortuitously demonstrate infection, but they provide too little tissue to interpret and categorize the histological changes confidently. Ideally, the patient is sufficiently stable to undergo video-assisted thoracoscopic surgery (VATS). This provides tissue that the pathologist can immediately dissect under sterile conditions so that focal lesions can be cultured for bacteria, fungi, and viruses; imprints and postoperative frozen sections can be studied using special stains (see the Infection section below), and the most informative areas can be submitted for fixation and permanent sections.

Historically, pulmonary complications have developed in one-quarter to half of allograft recipients and have frequently been fatal. Improvements in antimicrobial prophylaxis and therapy have dramatically decreased the incidence of viral pneumonias, although these can still develop through reactivation of latent infection and also through community exposure. A paramyxovirus, human metapneumovirus (hMPV), infects a significant proportion of transplant patients and can cause fatal pneumonia [161]. The exact nature and extent of its role in pneumonias previously classified as idiopathic are under study. Cytopathic tissue alterations diagnostic for hMPV have not been described, so antibodies for IHC need to be developed.

Interstitial pneumonia syndrome

Approximately 5–15% of allogeneic HCT recipients develop the interstitial pneumonia syndrome (IPS) in which there are multilobar infiltrates by X-ray or scan, symptoms and signs of pneumonia with evidence of abnormal physiology, and absence of active lower respiratory tract infection [162,163]. IPS is a generally severe and often fatal acute process, in contrast to the insidious chronic course of disorders such as usual interstitial pneumonia of Liebow. The histopathology of IPS is variable in both pattern and severity and may include diffuse alveolar damage with hyaline membranes, interstitial lymphocytic infiltration, increased alveolar macrophages, and pulmonary hemorrhage. These cases probably have a multifactorial etiology, which may include cytokine-induced damage [164], toxicity from therapy [165], cell-mediated injury, and occult infection [166,167]. The decreased incidence of IPS after reduced-intensity regimens strongly suggests that conditioning therapy can play a crucial role [168]. Alkylating agents such as cyclophosphamide and busulfan have long been implicated in pulmonary toxicity. There is now increasing evidence that high-dose melphalan [169] and also tyrosine kinase inhibitors such as dasatinib [170] may also cause lung damage. Acute GVHD is a risk factor for IPS [162,171]. However, IPS has not been firmly linked to an allogeneic reaction in humans, although there is evidence in mice that non-bacterial pneumonia is a combined effect of GVHD and radiation [172]. Pulmonary cytolytic thrombi (PCT) is an uncommon complication that presents radiographically as nodules or interstitial infiltrates [173]. Histologically, small- to medium-sized distal vessels are engorged by necrotic cytolytic cellular debris composed of monocytes that include an increased percentage of recipient origin relative to the percentage in the peripheral blood [174].

Pulmonary GVHD

The lung is a chronic GVHD target organ. Bronchiolar epithelium is evidently the major target tissue, although cellular damage is often difficult to identify in the epithelial monolayer. In contrast, there is no well-defined histologic pattern for acute pulmonary GVHD. Allo-reactivity may contribute to the non-specific features of cytokine-mediated damage and inflammation that characterize the IPS [165]. In a recent study, Xu et al. analyzed early histologic changes present in lung biopsies from patients with suspected GVHD and described three histologic patterns of pulmonary GVHD (acute lung injury, organizing pneumonia, and chronic interstitial pneumonia) [175]. All three histologic patterns are characterized by intrabronchiolar T cells, apoptosis, and perivenulitis, which help to distinguish GVHD from infections. The significant association of idiopathic bronchiolitis obliterans organizing pneumonia (BOOP) [also designated cryptogenic organizing pneumonia (COP)] with acute skin GVHD and also chronic GVHD of the gut and oral cavity in a large case–control study [176] indicates that this bronchiolocentric injury pattern with polypoid masses of granulation tissue obstructing the small airways (Figure 26.73) could represent a transition between acute

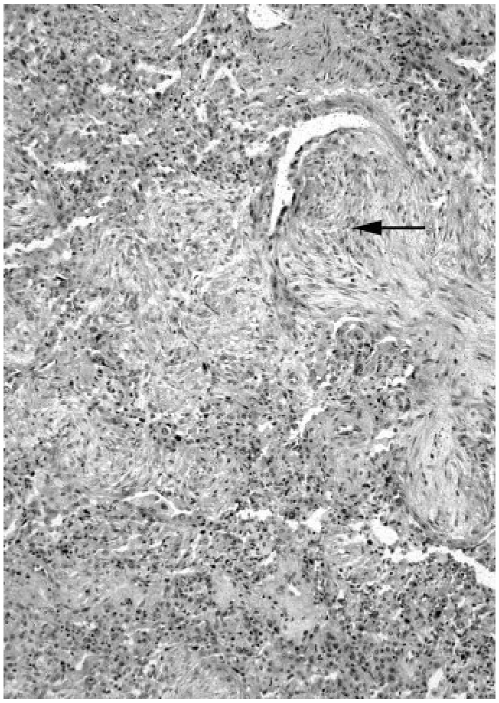

Figure 26.73 Lung, idiopathic bronchiolitis obliterans organizing pneumonia (BOOP) [or cryptogenic organizing pneumonia (COP)], day 120 following marrow allograft transplantation. The patient developed dyspnea and a cough following tapering of corticosteroid therapy for chronic GVHD. A chest X-ray showed multifocal alveolar opacities clinically suggestive of fungal or viral pneumonia. The biopsy demonstrated areas of consolidation in which bronchioles were blocked by granulation tissue (arrow) that also extended into nearby alveoli and was associated with interstitial and alveolar infiltration by mononuclear inflammatory cells. In HCT recipients, BOOP is associated with GVHD in the skin, oral mucosa, and gut [172].

and chronic phases. In the 49 patients with BOOP, day 108 was the median day of occurrence.

The diagnostic feature of pulmonary GVHD, constrictive bronchiolitis obliterans (CBO) (Figure 26.74) resembles lung allograft rejection where the small bronchioles contain intraluminal connective tissue with chronic inflammation that evolves into dense fibrotic scarring with luminal narrowing [167,177,178]. Secondary changes result in mucostasis, aggregates of foamy macrophages and late developing bronchiectasis. Stains for elastin such as the Verhoeff-Van Gieson and trichrome are helpful in demonstrating the scarred bronchioles. The end stage lung of patients dying of pulmonary GVHD may present a complex picture with loss of small airway and large airway disease including bronchiectasis and fibrosis secondary to repeated infections. It has become clear that the clinical bronchiolitis obliterans syndrome (BOS) encompasses several small airway disorders with differing stages of bronchiolar inflammation and fibrosis ranging from lymphocytic bronchiolitis (Figure 26.75) to complete fibrous effacement of the lumen (Figure 26.76). Two clinicopathologic studies of open lung biopsies in patients with suspected BOS and pulmonary chronic GVHD have demonstrated discrepant findings between the clinical 2005 NIH diagnostic criteria and the histology [179,180]. In the absence of signs of GVHD elsewhere, an open lung biopsy is recommended in the updated 2014 NIH document [81] (see Table 26.1).

Other sites involved in chronic GVHD

Several infrequent manifestations associated with chronic GVHD resemble autoimmune disorders, including vitiligo, myositis (Figure 26.77), serositis, arthritis, synovitis, myasthenia gravis, and bullous pemphigoid. Rackley et al. described a series of 12 patients, with a literature review of cardiac manifestations [181]. Striking findings included an obliterative coronary artery vasculopathy resembling that of cardiac allograft rejection (Figure 26.78) and myocarditis, associated with bradycardia and, in some instances, sudden death. A nephrotic syndrome is associated with membranous nephropathy and minimal change podocytopathy [182] are now regarded as manifestations of chronic

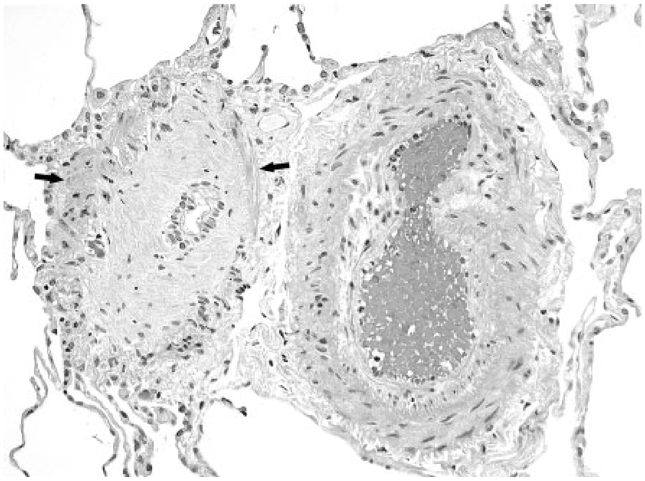

Figure 26.74 Bronchiolitis obliterans with constrictive subepithelial fibrosis at 5 years post allograft transplantation. The patient had developed obstructive pulmonary dysfunction. This biopsy confirmed that chronic pulmonary GVHD had developed following a history of skin and GI involvement. The arrows indicate smooth muscle bundles. There is also subintimal thickening of the accompanying artery.

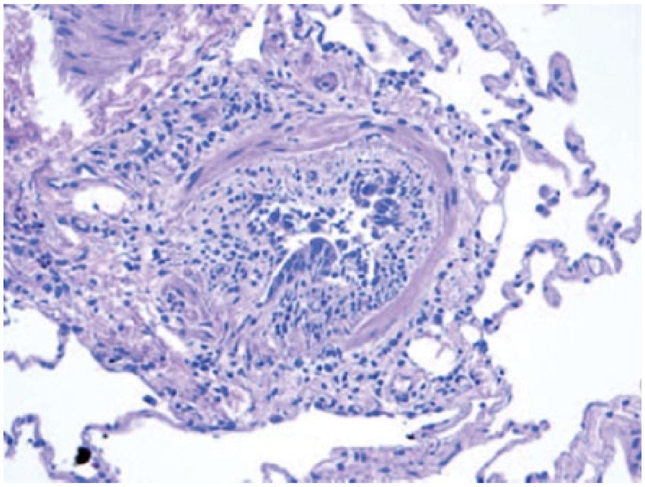

Figure 26.75 Bronchiolitis with evolving subepithelial fibrosis and lymphohistiocytic infiltration. There is marked epithelial damage. In this patient with chronic GVHD and obstructive pulmonary function abnormalities, the alterations are consistent with pulmonary GVHD. Similar changes could be seen in respiratory virus infection, which was absent in this biopsy. The ongoing inflammation and subtotal constrictive obliteration of this airway suggest that immunosuppressive therapy may be beneficial. (For a color version of this figure, please see the color plate section.)

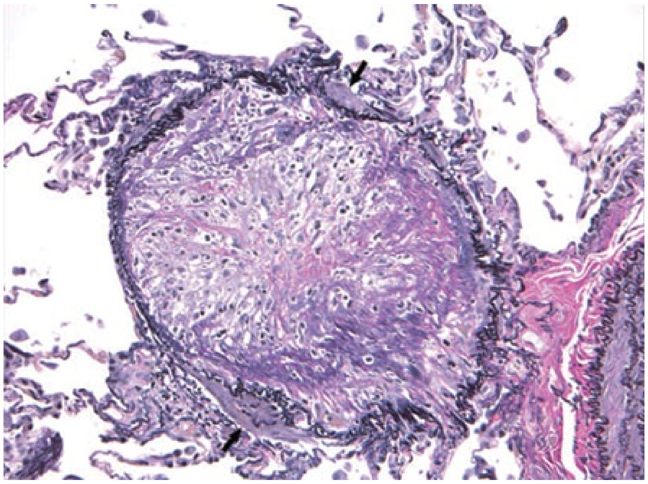

Figure 26.76 In a patient with a history similar to the preceding case (see Figure 26.75), the bronchiolitis obliterans of chronic pulmonary GVHD has progressed. This bronchiole is completely occluded by granulation tissue, and scattered mononuclear inflammatory cells are present. Without successful intervention with immunosuppressive therapy, this airway will finally probably be replaced by permanent scar tissue. The arrows indicate residual smooth muscle. The elastin fibers are black with this Verhoeff–van Gieson stain. (For a color version of this figure, please see the color plate section.)

GVHD (see Chapter 96 by Hingorani). Kamble et al. [183] and Grauer et al. [184] reviewed the literature on central nervous system lesions associated with chronic GVHD, including vasculitis neuropathy, demyelination, and immune mediated encephalitis. The NIH consensus on criteria for the diagnosis of chronic GVHD recommends that the diagnosis of chronic GVHD of the nervous system can be made only when other organs are affected by GVHD and neurologic differential diagnoses such as drug-induced toxicities or opportunistic infections are excluded.

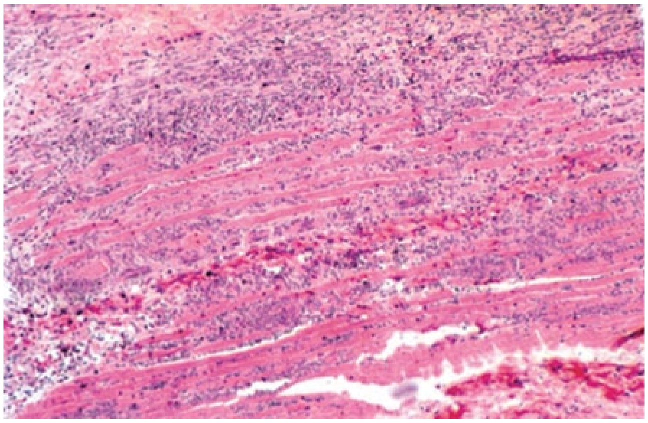

Figure 26.77 Polymyositis in deltoid muscle biopsy associated with chronic GVHD, day 1129. There is extensive endomysial chronic inflammation associated with myocyte destruction. The condition responded to immunosuppressive therapy. (For a color version of this figure, please see the color plate section.)

Infection

Infection remains a major cause of morbidity and mortality after HCT, which must be evaluated promptly and extensively in tissue and cytology preparations. The pathologist must be prepared to identify common pathogens and unexpected microorganisms, not just those suggested on the basis of non-specific clinical findings. *Helicobacter pylori* should be considered in all inflamed gastric biopsies (Figure 26.79). However, *Helicobacter* infection is

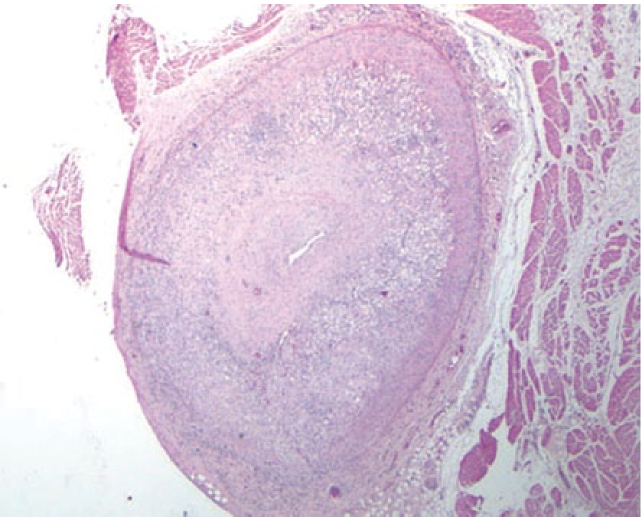

Figure 26.78 Coronary arteriopathy associated with chronic GVHD in a 15-year-old who died of myocardial infarction preceded by severe anginal symptoms. The lumen and muscular wall of all the major coronary arteries were subtotally to completely obliterated by a cellular infiltrate of lymphoid and monocytoid cells admixed with extracellular matrix. (For a color version of this figure, please see the color plate section.)

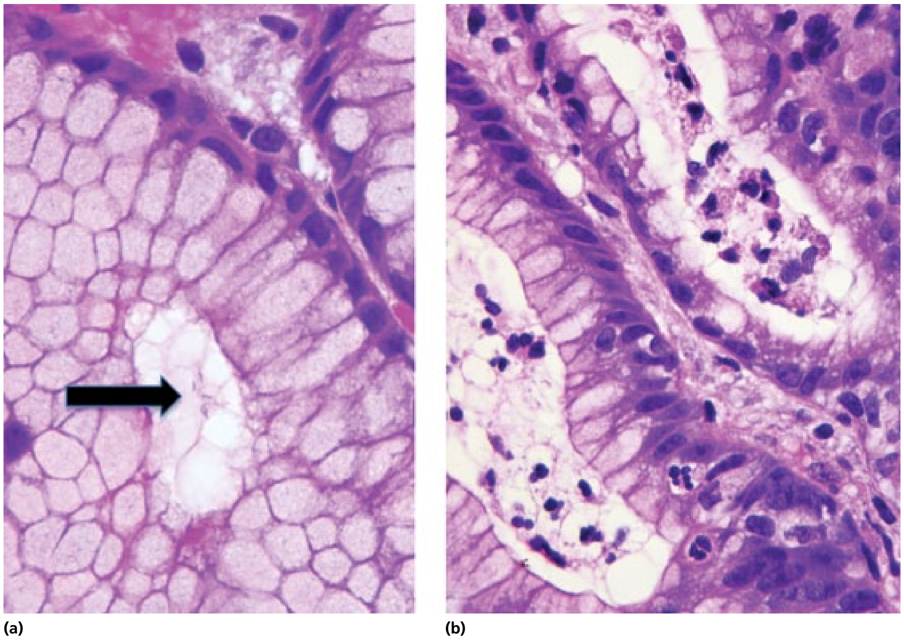

Figure 26.79 Gastric biopsy stained with H&E in a patient with chronic myeloid leukemia, day 37 post-HCT with persistent nausea and erythematous gastric lining by endoscopy non-responsive to steroids. (a) Gastric glands with a group of *Helicobacter pylori* organisms (black arrow) confirmed by immunohistochemistry. (b) Adjacent glands showing acute inflammation and a few *H. pylori* organisms. (For a color version of this figure, please see the color plate section.)

not common in post-transplant patients and specific stains are not routinely performed in post-transplant gastric biopsies at our institution. Although a nodular pulmonary infiltrate may indeed be the result of fungal infection, other treatable causes include nocardiosis, legionellosis, toxoplasmosis (Figure 26.80), and CMV (Figure 26.81), in addition to other viral pneumonias. It is obvious, but bears repeating, that identifying microorganisms requires looking specifically for them. This must be done quickly in immunocompromised patients if effective therapeutic drug levels are to be established. Since pneumonia can progress with devastating speed in HCT patients, lung tissue and/or lavaged cells should be immediately processed, stained, and evaluated. The modification of the original Grocott methenamine silver staining method by using heat has shortened the staining time from hours to less than 30 minutes, allowing rapid diagnosis of fungal and pneumocystis organisms. The pathologist does a disservice to the patient, and also to clinicians, by studying only H&E-, Gram-, and silver-stained sections and reporting that there is no evidence of infection. The preliminary stains include Wright–Giemsa, Papanicolaou, H&E, Gram, methenamine silver, PAS, modified Gimenez for *Legionella*, and Kinyoun for mycobacteria. Fite and Warthin–Starry stains and also a large number of IHC antibodies and in situ hybridization probes for organisms are used as needed. Control special stains are also needed to verify results.

Allograft recipients who received myeloablative conditioning and have GVHD are at significant risk for reactivation of latent viruses, especially members of the herpes virus group and adenovirus [185–187]. We now rarely see CMV or HSV in bronchoalveolar lavages or tissue biopsies because seropositive patients receive prophylactic antiviral therapy, and patients who develop antigenemia or PCR positivity are treated preemptively. However, treatment does not eradicate these viruses, so late infection may develop unnoticed after treatment is stopped (Figure 26.82). Late CMV pneumonia (Figure 26.81) occurring at a median of approximately 24 weeks post-transplant is increasing [188]. HCT recipients are at high risk for acquiring potentially fatal respiratory virus infections when the community prevalence of agents such as respiratory syncytial virus (RSV) (Figure 26.83) is high.

Occasionally, viral infection of a single organ will produce an ambiguous clinical presentation best resolved by prompt biopsy and rapid tissue evaluation. For example, severe abdominal pain may suggest impending bowel infarction but may actually represent acute herpes simplex virus (HSV), varicella-zoster virus (VZV) (Figure 26.84) or adenovirus hepatitis (Figure 26.85), which can be diagnosed within a few hours by histologic studies

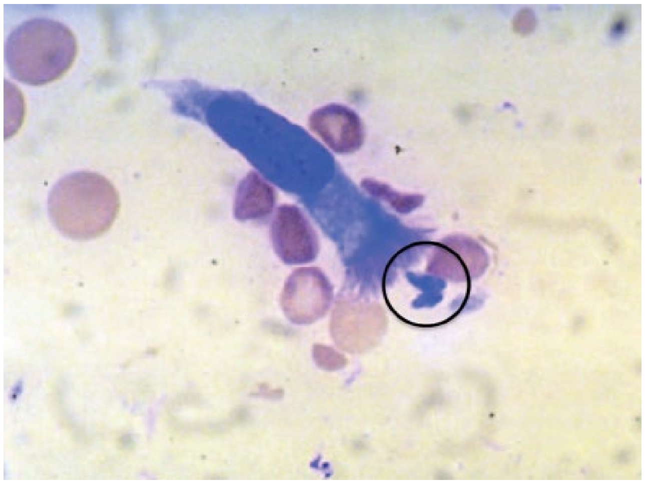

Figure 26.80 Two *Toxoplasma* tachyzoites (inside the circle) are present near the ciliated surface of a bronchial epithelial cell. Diagnosis of *Toxoplasma* pneumonia was established in less than 2 hours after bronchoalveolar lavage. Wright–Giemsa stain of cytospin preparation. (For a color version of this figure, please see the color plate section.)

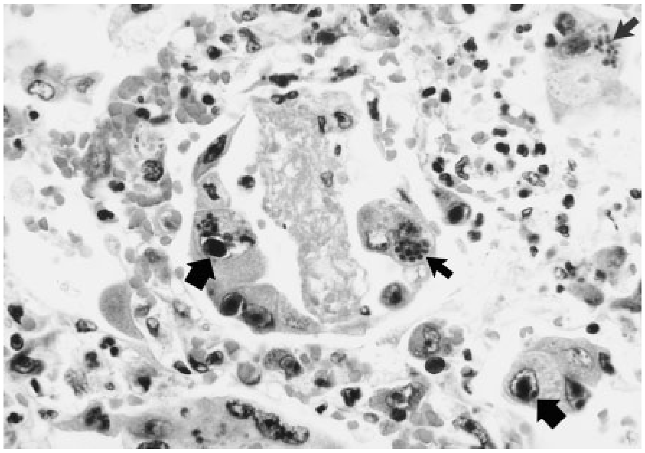

Figure 26.81 Lung, cytomegalovirus (CMV) pneumonia, day 68. Several large cells contain Cowdry type A nuclear inclusions (large arrows) and 6–12 smaller cytoplasmic inclusions (small arrows) diagnostic for CMV infection. (H&E.)

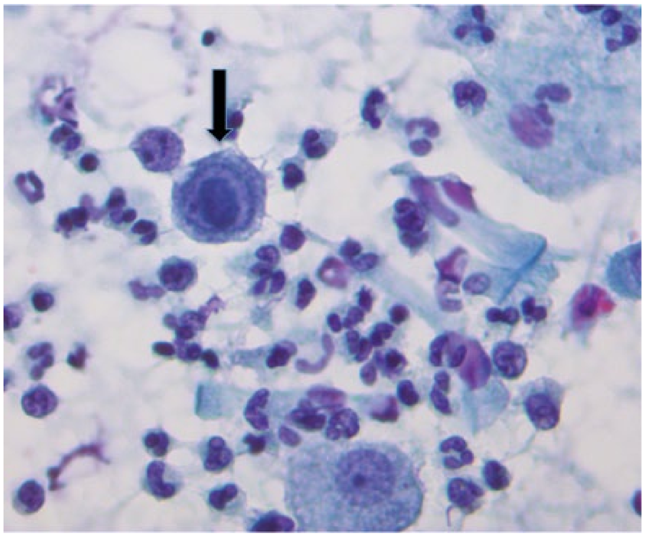

Figure 26.82 Cytomegalovirus cytopathic changes seen in a cytospin preparation of a bronchoalveolar lavage in a patient with B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma. Among a neutrophilic background is an infected alveolar macrophage (arrow) which demonstrates some cytoplasmic inclusion and a markedly enlarged nuclei with a single prominent enlarged central nucleoli. There is a relatively normal alveolar macrophage at the bottom middle of the picture for comparison. (For a color version of this figure, please see the color plate section.)

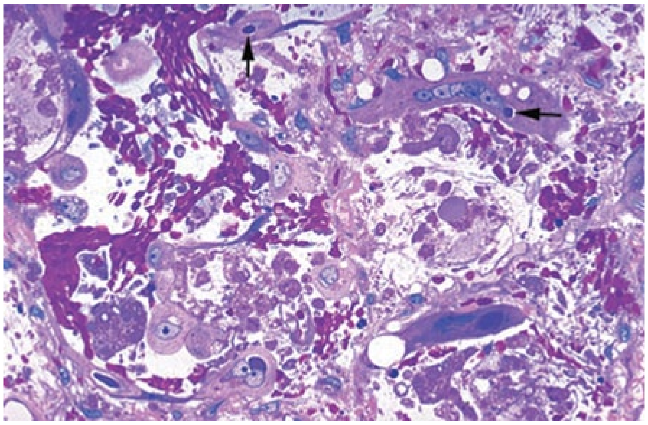

Figure 26.83 Respiratory syncytial virus (RSV) pneumonia in a lung biopsy, day 48. The presence of dark purple cytoplasmic inclusions in multinucleated epithelial cells (arrows) suggests the diagnosis but may be found with other viruses such as parainfluenza. During severe community outbreaks, infections may spread to hospitalized marrow recipients. (For a color version of this figure, please see the color plate section.)

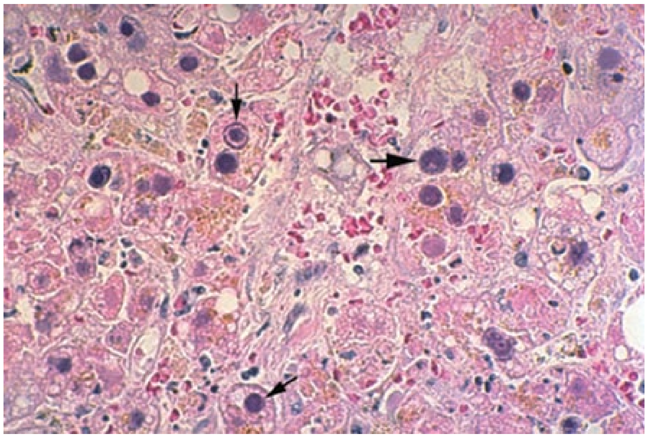

Figure 26.85 Overwhelming adenovirus hepatitis at autopsy 92 days after allogeneic BMT for AML. Dark basophilic nuclear inclusions produce "smudge cells" (large arrows) with blurred nuclear margins. Occasional cells with a halo around the inclusion (small arrow) suggest a combined infection with CMV, which was confirmed by isolation of both viruses. (For a color version of this figure, please see the color plate section.)

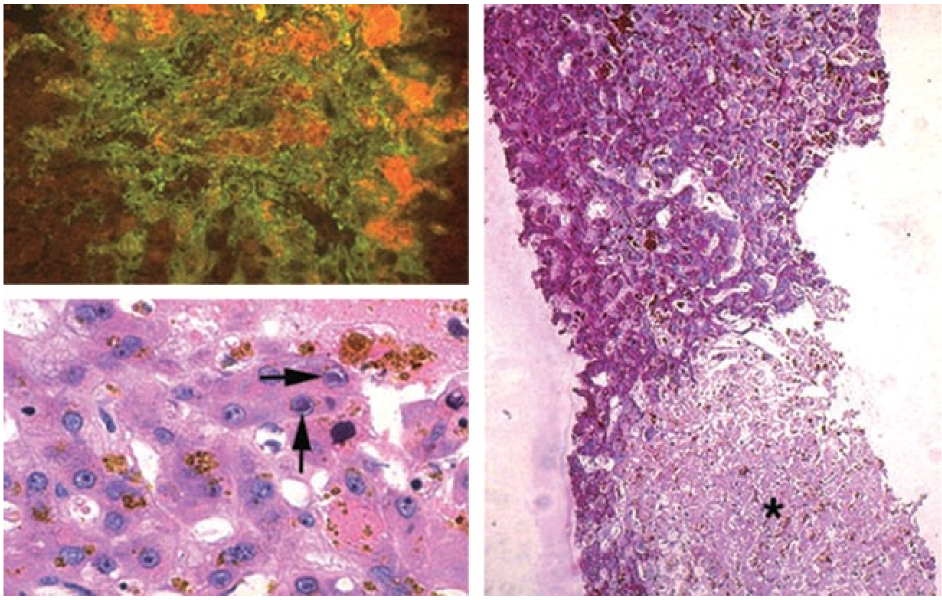

Figure 26.84 Varicella zoster virus (VZV) hepatitis in a percutaneous needle biopsy, day 79. On the right, a PAS stain demonstrates a pale necrotic area (*) bordered by cells containing nuclear inclusions (large arrows) visible by H&E stain on the lower left. Immunofluorescence confirmed the presence of VZV (upper left), and intravenous acyclovir was begun within hours of the biopsy. (For a color version of this figure, please see the color plate section.)

of a transjugular liver biopsy. Similarly, hematuria accompanied by costovertebral angle tenderness may be secondary to adenoviral nephritis (Figure 26.86), which can be diagnosed by renal biopsy [189]. Parvovirus infection should be ruled out in post-transplant patients with non-recovering or decreasing hematocrit/hemoglobin (Figure 26.20) [190].

The pathogenicity of human herpes virus type 6 (HHV6) and its impact on GVHD and other complications is complex [101,102, 191,192] (see Chapter 92). HHV6 can produce severe encephalitis, but viremia may not be necessarily associated with any clinical complications. The virus can be identified in tissues by PCR but results using in situ hybridization have been inconsistent. Identification of HHV6 in tissue sections by immunostaining with antibodies has been reported in a case of acute hepatitis [191].

Invasive mold infection develops in approximately 15% of patients undergoing either high-dose or reduced-intensity regimens. The most frequent cause is *Aspergillus*, followed by Zygomycetes and *Fusarium* species [193] (Figures 26.87–26.89) The histological demonstration of fungi in tissue is often crucial to the diagnosis and prompt treatment of invasive infection since fungemia is sporadic, and assay results for antigenemia are often inconclusive. Although not the most sensitive test, a bronchoalveolar lavage may show

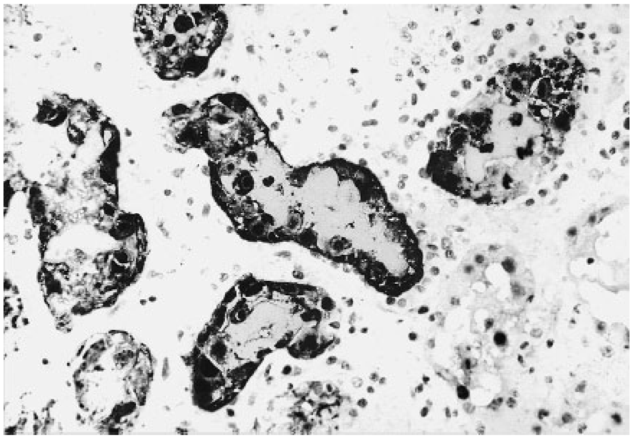

Figure 26.86 Kidney, adenovirus (ADV) nephritis, day 77. Tubules lined by degenerating epithelial cells are strongly reactive for ADV antigen by indirect immunoperoxidase staining using a monoclonal antibody to the adenovirus hexon protein (Chemicon International, Inc., Temecula, CA, USA). ADV species 11 was isolated in culture. Possible ADV nephritis should be considered in patients with hematuria and positive urine culture [189].

fungal infection and provide a comparatively rapid and specific result (Figure 26.90). Speciation using PCR has partially supplanted culture isolation, which is slow and insensitive. *Toxoplasma gondii* (Figure 26.80), *Pneumocystis jirovecii* (Figure 26.91), mycobacteria, *Nocardia* (Figure 26.92), and *Legionella* are also organisms that can be identified rapidly by histological and immunocytochemical staining and then specifically treated [194–196]. Although these organisms are unusual in most patient populations, their rapid identification can save lives. The incidence of toxoplasmosis over a 20-year period in Seattle was 0.3% [196], of nocardiosis over 25 years 0.2% [196], and of legionellosis over 12 years 0.6% [194].

Additional comments

Since final submission of this chapter several new developments have occurred, which could not be incorporated in the main body of the text. These include the updated 2015 NIH clinical and histologic criteria which indicate the need for open lung biopsy only if clinical tests consistent with the bronchiolitis obliterans syndrome are not associated with any existent manifestations of active GVHD. Small airway disease related to chronic GVHD affects up to 10% of long term survivors and may have a continuum from lymphocytic bronchiolitis to constrictive bronchiolitis obliterans as the final common pathway. Unusual complications like myositis and bronchiolitis obliterans pneumonia are classified as lesions of uncertain significance. To improve interobserver reproducibility, recommendations for the final histologic assessment for GVHD have been simplified into three categories: "No GVHD," "Possible GVHD" and "Likely GVHD". The "likely" GVHD category combined the previous categories of "consistent with" and "diagnostic of" GVHD. The cord colitis syndrome story emphasized the lesson to use standardized histologic definitions of GVHD and that infection and GVHD are not mutually exclusive. Certain kidney lesions, membraneous nephropathy and minimal change disease are now regarded as manifestations of chronic GVHD.

CHAPTER 27

Biostatistical Methods in Hematopoietic Cell Transplantation

Joycelynne M. Palmer[1] **and Ted A. Gooley**[2]
[1]City of Hope National Medical Center, Duarte, CA, USA
[2]Fred Hutchinson Cancer Research Center and University of Washington, Seattle, WA, USA

Introduction

With the tremendous strides made in the field of hematopoietic cell transplantation (HCT), advances in study design and biostatistical methodology are required to keep pace. Clinical trial design and analysis methodology continue to evolve, allowing HCT practitioners to conduct studies that lead to the most scientifically rigorous and defendable conclusions possible given the particular setting. This chapter, designed for a clinical audience, provides an overview of the biostatistical methods commonly used in HCT studies, both prospective and retrospective. We focus on the concepts, procedures, and interpretations of specific study designs and statistical analyses, from the phases of clinical trials through observational studies as applied to HCT. The principles for designing such studies and the fundamentals regarding study conduct are described, along with the subtleties, strengths, and potential pitfalls of various study designs and analytic approaches. It is assumed that the reader is acquainted with the usual concepts of a beginning course in statistics: probability, estimation of parameters, hypothesis testing, and confidence intervals; if not, suggested reading for an introduction to biostatistics includes books by van Belle et al. [1] and Zar [2].

Formulas and calculations are used minimally in this chapter, presentation instead favoring the underlying concepts and theories of biostatistical methodology. It is hoped that this approach will provide physicians, fellows, medical students, and healthcare professionals involved in HCT research with a basic understanding of, and guide to, appropriate approaches in the design, conduct, and statistical analysis of studies in HCT. The chapter is not meant to be exhaustive and detailed, as space constraints do not allow such an exposition and the authors appreciate that any planned research study would be developed and carried out in collaboration with a biostatistician. For those seeking a more detailed treatment of the history, rationale, and methodology underlying observational studies and clinical trials, the texts by Meinert and Tonascia [3], Pocock [4], Friedman et al. [5], Rosenbaum [6], Kelsey et al. [7], and Piantadosi [8] provide such elements. It is our intention to leave the reader with sufficient knowledge and guidance to continue to pursue topics of interest using the basic texts and articles referenced in this chapter.

Statistical methods in HCT research

Survival analysis

The term "survival analysis" is often used to describe a collection of statistical methods developed for the analysis of data in which the outcome under study is time until a prespecified event occurs (commonly referred to as time-to-event data). The occurrence of this event is typically referred to as a "failure," although the event can be considered a positive clinical outcome, such as engraftment or response to treatment. In HCT research, treatment "success" is often assessed by measuring the number of surviving patients following the intervention over some specified period of time, with the study objectives typically focused on the ability of the treatment to prevent or delay failure (e.g. disease relapse, death).

While most early phase I and II studies focused on shorter-term binary end-points such as toxicity or disease response, observational studies in HCT and phase III studies typically utilize longer-term events, such as time to relapse or survival time after transplant. The survivor function, *S(t)*, is defined as the probability that survival exceeds some specified time *t*, namely

$$S(t) = Prob(T > t) = 1 - Prob(T = t) = 1 - F(t)$$

where $F(t)$ is called the cumulative distribution function (CDF) of mortality. $S(t)$ is also defined as a function of the hazard of failure, where the hazard function at time *t* represents the instantaneous failure rate at *t* among patients who have survived to *t* without failure or, roughly speaking, as the probability of death within a small window among those who are at risk of failing within this window. In a study with a time-to-event outcome, each patient will contribute data consisting of (1) time from HCT (or study entry) to event (or last contact-evaluation date/study end date) and (2) event status (i.e. failure: yes/no). Any patient who does not experience failure by the time of analysis is said to be "censored," as all that is known for that patient is that the event did not occur as of the last contact date, although failure can occur at a point beyond the censored time. This form of censoring is referred to as "administrative" censoring, because the incomplete information on the patient is due to the administration of the study, rather than to any irregularities in the data collection or ability to follow the patient through the study period.

Kaplan–Meier survival estimate

If all patients have complete follow-up (i.e. there is no censoring), the survival estimate at time *t* is the simple proportion of patients alive at *t* divided by the number enrolled. If censoring occurs,

however, one must appropriately take into account the observation time of the censored cases in order to obtain an unbiased estimate of survival. The Kaplan–Meier (KM) method [9] accomplishes this and is the most widely used approach for computing survival estimates. For each ordered failure time, the estimated survival probability is calculated using the product-limit method, with the following equation:

$$\begin{aligned}\hat{S}\left(t_{(j)}\right) &= \prod_{i=1}^{j} \hat{Pr}\left(T > t_{(i)} \middle| T \geq t_{(i)}\right) \\ &= \hat{S}\left(t_{(j-1)}\right) \times \hat{Pr}\left(T > t_{(j)} \middle| T \geq t_{(j)}\right)\end{aligned}$$

where T is the random variable for the subject's survival time, t is any specific value of interest for the variable T, and $S(t)$ is the survival function, $S(t) = Pr(T > t)$.

KM estimates of survival probabilities, when graphed, yield a "curve," also referred to as a "step function," that drops down a fraction of its value at each failure time and which, when a large enough sample is taken, approaches the true survival function for that population. Censored observations are commonly denoted by vertical tick marks on the curve. Figure 27.1 provides an example of a KM overall survival curve with censoring. Data for this example were derived from an unpublished study of survival times (in years), post-transplant, among patients with leukemia.

The plots of the survival probabilities correspond to each ordered failure time. KM plots start at a survival probability of 1, with all patients alive (no failures) at $t = 0$, and then drops down some fraction as we move from one ordered failure time to the next. Several statistical software packages are available to compute and plot survival probabilities over time, based on the number of patients at risk, number of failures, and number of censored persons at a given time.

Among HCT patients, the hazard of death near the time of HCT is much higher than the hazard at a time further away from HCT (the majority of deaths following HCT occur within the first 100–365 days post-transplant). As a result, the survivor function tends to plateau or semi-plateau at time points further from the time of transplant. Unfortunately, interest is often highest where the data are the least informative – at the end of the curve where few patients are still at risk, resulting in a variance in the estimate that is higher than at earlier time points. This uncertainty should be quantified by reporting either point-wise confidence intervals (CIs) or confidence bands. Standard errors can be computed for the KM curve at any time point, and the estimated survival curve graphed with a *plus* and *minus* distance (usually 95% CIs) around the curve at a few time points to reflect the range of the true survival probability.

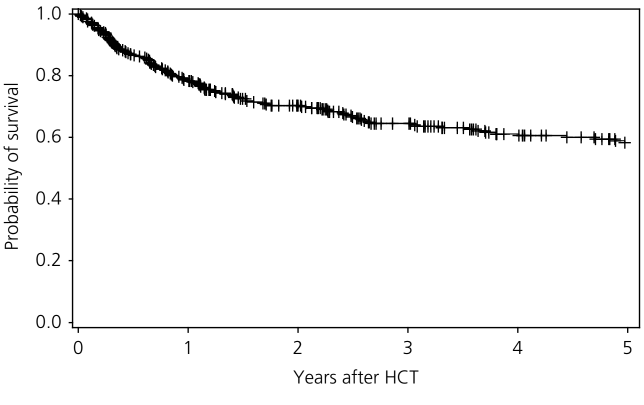

Figure 27.1 Kaplan–Meier (KM) overall survival curve.

Competing risks

We define a competing risk as the occurrence of an event that precludes the event (outcome) of interest from occurring. For example, if relapse is the event of interest, death without relapse [i.e. non-relapse mortality (NRM)] is a competing risk. The only end-points in HCT that do not have competing risks are overall survival (where failure is the occurrence of death) and failure for event-free survival (where failure is often defined as death or relapse, whichever occurs first). When estimating the probability of an event by a specified time that has competing risks, one must take care in how the competing-risk event is handled. Kalbfleisch and Prentice [10] recognized this as early as 1980, introducing what they denoted the cumulative incidence function (CIF). Despite this, it was not uncommon for investigators to use the complement of the KM estimate (1 – KM) inappropriately to estimate the probability of failure, where competing-risk failures are incorrectly censored. Because of this, Pepe and Mori [11] illustrated the flaw in the KM method for these purposes with examples focused on the field of HCT. Many other authors have written on this subject in the last two decades (e.g. [12–17]). Investigators are encouraged to review these published examples for instructional purposes. Nonetheless, one can still find recent instances where 1 – KM is used in error, disregarding the presence of competing-risk failures.

According to the definition of a competing risk, such failures are not capable of subsequent failure from the event of interest, but censored observations are implicitly assumed to be capable of failure at a time beyond the censored time. Therefore, 1 – KM results in an estimate that is larger than it should be. To illustrate better the differences in the cumulative probability of the cause-specific failure estimates produced by the two estimators (1 – KM and CIF), data from a study of relapse post-transplant, among patients with leukemia, are provided in Figure 27.2.

The graphs are identical for the majority of the first year post-transplant, given that there are very few competing events before $t = 0.96$ years; at $t = 0.96$ years the 1 – KM estimate is 0.18 and the CIF estimate is 0.17. The difference becomes more obvious after 3 years and increases with more competing events (e.g. death without relapse); at $t = 3.13$ years the 1 – KM estimate is 0.25 and the CIF estimate is 0.22.

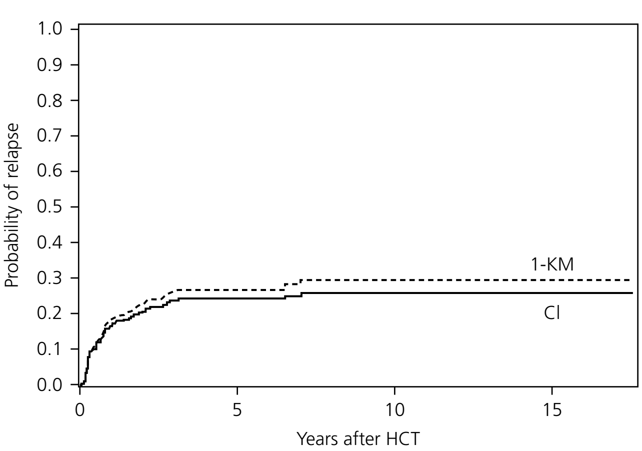

Figure 27.2 Cumulative probability of relapse produced by two estimators, 1-KM and CIF.

As stated earlier, this has been shown in several reports, including by Gooley et al. [14], which used the redistribute-to-the-right concept to demonstrate how 1 – KM fails. Briefly, their argument is as follows. With complete follow-up (i.e. all subjects are known to have failed or not failed by a specified point in time), the contribution of a single failure to the estimate of the probability of failure is simply $1/n$, where n is the number of patients being studied. If a patient is censored, however, and therefore capable of failure at a later time, this contribution of $1/n$ is uniformly redistributed among all patients who remain at risk beyond the censored time. As a result, subsequent failures contribute $1/n$ plus this redistributed amount to the estimate of the probability of failure. If a patient fails from a competing risk, 1 – KM censors this observation and the potential contribution of the censored observation is inappropriately redistributed among those who are at risk of failure beyond the competing-risk failure time. On the other hand, the cumulative incidence function correctly treats such a patient as a non-failure from the event of interest since such an observation has complete follow-up by this time, that is, it is known that this patient has not failed by this time and will not fail from the cause of interest beyond this time. Since 1 – KM does not distinguish between censored observations and competing-risk failures, it depends only on the hazard of failure from the cause of interest. The CIF makes such a distinction, however, and it therefore depends on the hazard of failure from the cause of interest in addition to the hazard due to the competing risk.

Testing of group differences for time-to-event end-points

Beyond estimation, one is ultimately interested in comparing outcomes between two or more groups. There are many ways to do this, but the most common method for time-to-event data that do not contain competing risks is the log-rank test [18], which is used to determine whether or not the KM curves (or survivor functions) from two or more groups are statistically equivalent. The null hypothesis is that there is no overall difference between the two survivor functions; the alternative hypothesis is that there is an overall difference between the two survival curves. The calculation of the log-rank statistic involves the formation of a 2 × 2 table at each failure time (one row each for groups A and B; one column each for lack of failure and failure), and within each table the number of observed failures is compared with the expected number under the null hypothesis of no difference. These comparisons are summed together across the times of failure, and a weighted version of this sum forms the log-rank test statistic. Under the null hypothesis, this test statistic follows a chi-squared distribution with one degree of freedom.

The log-rank test compares the survivor functions, but given the dependence of $S(t)$ on the hazard function, it equivalently compares the hazards between groups. In fact, the observed and expected numbers of failures that contribute to the log-rank test statistic are derived from estimates of the hazards of failure at the specified time. We also note that the log-rank test, as the name implies, is a rank-based test. Provided that the relative order of failures and censored times in group A versus group B remain the same, the actual values of the times will not change the log-rank test statistic.

Because high early mortality followed by a relative plateau is a common survival pattern following HCT, inferences based on the log-rank statistic are not well suited to studying long-term survival, potentially reporting a long-term difference between study arms even though no long-term survival benefit exists. An alternative approach is to conduct a separate analysis of long-term survival, modeling the population as a mix of long-term survivors (the cured fraction) and patients undergoing an earlier failure process (the uncured fraction). Ultimately, cure-rate models produce an estimate of the cure fraction, where a probability of long-term survival is postulated [19,20]; such modeling techniques are now implemented in S-*plus* [21].

If one is comparing outcomes for time-to-event end-points with competing risks, the log-rank test is still valid, but it is important to understand what are being compared in such cases [22,23]. As previously stated, the survival distribution is a function of the hazard of failure, and therefore comparison of the survival distributions is tantamount to comparing the hazards of failure. When the log-rank test is used for end-points with competing risks, what are being compared are what are called the cause-specific hazard rates of failure, where competing-risk failures are censored. It can be confusing when told that for estimation purposes competing-risk failures are not censored, yet for inferential purposes such failures can be censored. The distinction arises from the fact that the hazard is fundamentally a conditional quantity. The cause-specific hazard of a specific failure type at a given point in time is conditional upon patients being at risk of failure from this type at that time, regardless of whether patients are not at risk due to lack of follow-up or due to failing from a competing risk prior to this time. The cause-specific hazard depends only on the hazard of failure from the cause of interest, but the CIF depends on the hazards of failure from both the cause of interest and the competing risk. Several tests have been proposed for comparing cause-specific CIFs, but the most common method was proposed by Gray [24]. Similar to the survivor function, defined as a function of the hazard, the (cause-specific) cumulative incidence function is defined as a function of the hazard of failure from both causes (i.e. each cause-specific hazard). One can define a hazard-like quantity of this CIF in a fashion similar to the cause-specific hazard. Commonly referred to as the subdistribution hazard, this differs from the cause-specific hazard function in that it represents the probability of failure from the cause of interest in a narrow time window but among patients who not only have survived without any failure up to this time but in addition among those who have failed from a competing risk prior to this time. In other words, patients who fail from a competing risk are not dropped out of the "denominator" as they are in the log-rank test when used to compare cause-specific hazards. In this sense, the CIF hazard function can also be thought of as the hazard of an artificial time variable T' defined as $T' = t$ if a failure from the cause of interest occurred at time t and $T' = \infty$ if failure from the competing risk occurred.

As an example, consider the case where the true cause-specific hazard of relapse for each of groups A and B is 0.1, and the cause-specific hazard for NRM for groups A and B are 0.1 and 0.3, respectively. Suppose we draw a random sample for each group under these parameters, and we further assume that there is no censoring. We then wish to compare relapse between groups. Since the log-rank test compares the cause-specific hazards of relapse, one would expect the conclusion from such a comparison not to yield a statistically significant difference (as the cause-specific hazards are identical). Moreover, because the cause-specific hazard of NRM is higher in group B than it is in group A, there should be a larger number of NRM failures in group B at a given point in time. This will lead to a lower hazard-like function for relapse (the so-called subdistribution hazard that Gray's test compares) in group B, that is, the "denominator" for group B will be larger than the "denominator" for group A due to the larger number of NRM failures (recall that the subdistribution hazard for relapse is calculated among patients who have survived without relapse *or who have failed from the competing risk of NRM*; since more patients in group B will have failed from NRM, the denominator for group B will be larger). One would expect, therefore, that Gray's test would yield a larger difference in relapse than would the log-rank test. One particular random sample of 200 per group yields the relapse and NRM cumulative incidence curves shown in Figures 27.3 and 27.4), with the proportion of each type of failure listed. The log-rank test comparing the cause-specific hazards of relapse yields $p = 0.71$, and Gray's test comparing the subdistribution hazards of relapse yields $p = 0.03$. Both the log-rank and Gray's test yield $p < 0.0001$ for the risk of NRM.

In summary, both Gray's test and the log-rank test are valid. The conclusions from each test can differ since they do not test the same hypotheses (as demonstrated in the example above), although in our experience the two tests lead to the same qualitative conclusion most of the time. The log-rank test compares cause-specific hazards, quantities that are conditional upon patients being at risk of failure from the cause of interest at time *t*, whereas Gray's test compares hazard-like functions (commonly referred to as subdistribution hazards) that are conditional upon patients being at risk of failure at time *t* or failing from the competing risk prior to *t*. As demonstrated above, situations in which the two tests could lead to qualitatively different conclusions include the instance where the (cause-specific) hazards of failure from the event of interest are roughly the same between groups, yet the (cause-specific) hazard of failure from the competing risk is much larger in one group than the other. There are many excellent references that explore and explain the differences between these tests, for example [12,23,25]. In practice, one should consider applying each test for end-points with competing risks, as each test contains important information. In addition, a comparison of failure from the cause of interest and a comparison of failure from the competing risk should be conducted. Finally, interpretation is made easier if one is able to use an end-point without competing risks (e.g. relapse-free survival as opposed to relapse or NRM), although we acknowledge that this is not always feasible and/or of interest.

Regression

When comparing two groups, it is often the case that various factors known to impact outcome are unequally distributed. Therefore, the observed difference in outcome may be due more to the difference in the distribution of these factors than to a true difference. In addition, rather than treatment defining the two groups, patients may instead be categorized as those who do well (e.g. survive) and those who do not do well (i.e. die), and one is then interested in identifying factors that distinguish such groups. Each of these situations calls for regression techniques. No matter what type of regression, it is assumed that the outcome being modeled (referred to as the dependent variable) is related to one or more factors (referred to as the independent/explanatory variables or covariates) via some functional form. The outcome and the nature of the functional form determine which type of regression one uses. Two of the more common techniques in HCT are logistic regression and Cox regression (discussed below). Regardless of the type of regression, however, one uses observed data to estimate the value of the coefficients associated with each explanatory variable; one then tests the hypothesis that the average value of that coefficient is equal to zero. If this hypothesis is rejected, then this factor is said to be statistically significantly associated with the outcome; otherwise, it is concluded that the value of this factor does little to impact outcome.

Healthy approach to modeling

The purpose of modeling (multivariable regression analysis) is to assess the effects of multiple explanatory variables (e.g. age, disease status, related/unrelated donor) on the outcome variable (e.g. overall mortality, relapse). As stated above, regression modeling can be used to identify important prognostic factors and/or to assess the significance of a given factor after adjusting for other risk factors, and the type of regression used depends on the outcome being modeled. There are many issues that need to be considered when fitting a multivariable regression model, and we touch on some of them below.

Explanatory variables (or covariates) will be modeled as either continuous or categorical with two or more categories. The choice of continuous or categorical will be largely dependent on how best to interpret the impact of an explanatory variable given what is already known and supported by the literature. If continuous, one has many options for modeling such a variable. One choice is to model that variable as a continuous linear variable, where the underlying assumption is that the change in outcome associated with a specified change in the covariate is the same, regardless of the starting value of the variable. If the data do not support such a model, one can instead assume a non-linear association, of which there are many choices. On the other hand, if the interpretation/application of a continuous explanatory variable is complex or the covariate is better supported by a categorical rendering, a continuous variable can also be categorized, and a frequently used approach for this is to group the variable as above or below the median value for the sample population. Using such a cut point is convenient, but there may not be a scientific rationale for doing so. With this approach, the assumption being made is that patients with a value below the median have roughly the same outcome as do patients above the median. If such an assumption is not supported by the data or the literature, alternative cut points (including the possibility of using more than one) should be explored. There is often a biological reason for grouping a continuous variable, and in such cases one should use these groupings. If a continuous variable is categorized based solely on the data in an effort to maximize the difference in outcome between categories, one needs to recognize that these categories in future studies are not likely to show as strong an association.

Variable selection and modeling specifications

There are multiple approaches for choosing which variables to include in a regression model; perhaps the most popular is the forward selection stepwise procedure. In such an approach, the variable that improves the fit of the model most is included first, provided that the improvement meets some threshold level of significance usually prespecified by the biostatistician with input from the study team. With this variable in the model, the significance of the remaining variables is assessed, and the variable that leads to the largest improvement in model fit is added. This process is continued until no other variables improve the model to the degree set by the threshold significance level. When a variable enters the model, some approaches also allow for variables previously entered into the model to exit if the significance level of the previously entered covariate exceeds some threshold level. Threshold values for entry are typically set at a level higher than 0.05 (e.g. 0.10), but there are no definite rules for this. The goal of such an approach is to identify the most parsimonious model from the list of factors examined. Because some variables are known from clinical experience and/or the literature to be important, one should give careful consideration to including these factors regardless of their statistical significance; a model that excludes factors known to impact outcome, more than likely, will be questioned. That said, there are limits to the number of covariates that can be included in a model, however. Rules of thumb have been proposed for Cox regression such that roughly 10 events are required for each parameter that is estimated in the model [26]. For logistic regression, similar rules of thumb have been proposed, with 5–10 failures or successes (whether it is failures or successes, generally fit and stability are determined from taking the minimum between total number of failures or successes in the study). Particulars for each study will dictate how many factors can be included, but investigators should be aware that the number is limited.

Once one has settled on a final model, presentation should include the appropriate comparative summary measure (e.g. hazard ratio for Cox, odds ratio for logistic) along with CIs, number of patients/events per group and p-value for the estimate and overall model. For categorical variables, the reference group should be noted (i.e. the category that the other category or categories is being compared with via the hazard or odds ratio).

As already mentioned, when assessing the association of a variable with outcome one interprets the result as the correlation when all other variables in the model are held constant, and it is assumed that this association is roughly the same across all levels of the other covariates. The association, however, may not be roughly the same across levels of other factors, in which case one says there is a statistical interaction. For example, the impact of an HLA mismatch (relative to being matched) may be different in patients with less severe disease than among patients with more severe disease. Such interactions can be tested, and in some cases the clinical question and associated biology help to dictate which interactions should be examined.

Logistic regression

Logistic regression is used when the outcome is binary. One then models a function, called the logit, of the probability that the binary outcome occurs as a combination of various factors. Mathematically, this function is as follows:

$$\operatorname{logit}(p) = \log[p/(1-p)] = B_0 + B_1x_1 + B_2x_2 + \cdots + B_nx_n$$

where the x_i are the explanatory variables, the B_i are the coefficients that are estimated from the observed data, and p is the probability of the binary outcome. Along with estimates of the B_i, one also obtains estimates of the variance of the B_i, and these taken together provide the strength of evidence on how likely it is that each B_i is equal to zero. The quantity $\exp(B_i)$ is called the odds ratio. The odds of the outcome is defined as the probability of occurrence of the outcome divided by the probability that the outcome does not occur [i.e. $p/(1 - p)$], and the odds ratio is simply the odds for group A divided by the odds for group B if x_i is a dichotomous variable. Odds ratios that are greater than 1 mean that group A is more likely to have the outcome than group B, and odds ratios less than 1 mean that group A is less likely to have the outcome than group B. If x_i is continuous, then the odds ratio is interpreted as the change in the odds of the outcome as x_i increases by one unit.

When one includes more than one explanatory variable in the regression model, the interpretation of the odds ratio is that it represents the relative odds of the outcome for group A versus group B after considering levels of the x_k, with $k \neq i$. It is assumed that the difference between A and B is roughly the same across all levels of these x_k. This is commonly referred to as multivariate regression, although the more technically correct description is multivariable regression.

Cox regression

There are various ways to model time-to-event data, but the most commonly used approach is known as Cox, or proportional hazards, regression. Mathematically, one assumes that the hazard of failure is related to a group of covariates according to

$$H(t) = H_0(t)\exp\left(B_0 + B_1x_1 + B_2x_2 + \cdots + B_nx_n\right)$$

where the B_i and x_i are as described above, $H(t)$ is the hazard function, and $H_0(t)$ is what is known as the baseline hazard. Similarly to logistic regression, if x_i is categorical with two categories, then $\exp(B_i)$ is interpreted as the hazard ratio, also commonly called the relative risk. This is simply the hazard of group A divided by the hazard of group B. As with logistic regression, the hazard ratio for a particular factor represents the relative hazards of failure when all other factors in the model are held constant.

There are more restrictive assumptions involved in Cox regression than in logistic regression. In particular, the functional form of the model assumes that the hazards between "groups" that are being compared for a particular covariate are proportional. The hazard of failure can increase and/or decrease with time, but the assumption is that this increase and/or decrease occurs proportionally in the groups. If this assumption is violated, then one needs to consider modeling this non-proportionality using a time-dependent covariate (see below) or choosing a fixed point in time and using logistic regression. One feature that Cox regression allows is to model explanatory variables as what are called time-dependent covariates. This is useful when modeling variables that can change throughout time. For example, if one is interested in assessing the impact of chronic graft-versus-host disease (GVHD) on mortality/survival, one must take into account the timing of chronic GVHD given that the patient's chronic GVHD status is not known at HCT. Essentially, patients with GVHD are considered to be in the non-GVHD group until they develop GVHD, at which point they join the group with chronic GVHD. Unfortunately graphical methods do not exist for time-dependent covariates, so if one wishes to display, for example, overall survival among patients with and without GVHD, one must choose a time post-transplant, categorize surviving patients to that time as having GVHD or not, and then plot survival from that point forward. This approach is referred to as a landmark analysis.

As an example of fitting a Cox regression model, we show some results from an analysis of 1007 MDS patients [27], with the goal of identifying risk factors for overall mortality. There were 650 deaths by last contact, providing considerable flexibility in the number of covariates that could be reasonably included in a model. A total of 15 demographic variables were examined (for the purposes of this example, we did not consider variables involving treatment of the disease), some continuous and some categorical, with the categorical variables each containing between two and 11 distinct groups. Table 27.1 summarizes the results of a stepwise regression analysis. Note that for variables with more than two categories, all parameters needed to describe such a variable fully need to go in or out of the model together. Note that in this particular example, year of HCT, patient age, and platelet count were each modeled as a continuous linear variable. Examination of the underlying assumptions indicate that this is a reasonable assumption for age, for example, with hazard ratios by decade relative to 0–30 years being 1.30 (for 30–40 years), 1.72 (for 40–50 years), 1.79 (for 50–60 years), 2.23 (for 60–70 years), and 3.98 (for 70 years and above). Note also that results for groups with "small numbers" for various factors were not presented ("small" was arbitrarily defined in this example as less than 20).

Competing-risks regression

Similarly to the discussion above concerning the log-rank test versus Gray's test when comparing outcomes with competing risks, if one needs to adjust for potential confounding or examine risk factors for outcomes with competing risks there are methods that model the cumulative incidence function rather than the cause-specific hazard function (which is what Cox regression does in the presence of competing risks). One such method was proposed by Fine and Gray [28], where, as in Gray's test, the Fine–Gray method distinguishes patients who are still alive (without failure of any type) from those who have failed from a competing cause, allowing for the appropriate estimation of the effects of the covariates on the cumulative incidence function. Similarly to the distinction between the log-rank test and Gray's test, interpretation of regression modeling for end-points with competing risks needs to consider what is being modeled: the cause-specific hazard for Cox regression, and the cumulative incidence function for Fine–Gray regression.

Table 27.1 Results from fitting a stepwise Cox regression model for overall mortality among 1007 MDS patients

Factor	*N* events/*N* at risk	Hazard ratio	95% CI, *p*-value
FAB/WHO classification[a]			
RA/RARS/RCMD	251/468	1	–
RAEB	211/302	1.48	1.22–1.80, $p < 0.0001$
RAEBT	73/89	1.56	1.17–2.07, $p = 0.002$
tAML	91/107	1.25	0.91–1.72, $p = 0.17$
MDS	8/20	0.89	0.42–1.90, $p = 0.76$
Disease category			
MDS	435/728	1	–
tAML/MDS	215/279	1.57	1.17–2.07, $p < 0.0001$
Five-group cytogenetic risk[b]			
Good	253/451	1	–
Intermediate	112/187	1.06	0.84–1.34, $p = 0.61$
Poor	113/176	1.21	0.95–1.55, $p = 0.12$
Very poor	107/123	2.56	2.01–3.31, $p < 0.0001$
Donor type			
Matched sibling	306/470	1	–
Non-sibling relative	59/77	1.26	0.93–1.71, $p = 0.14$
URD matched	155/266	1.20	0.96–1.50, $p = 0.10$
URD mismatched	110/158	1.54	1.21–1.95, $p = 0.0004$
URD unknown	20/36	1.05	0.65–1.68, $p = 0.86$
Etiology[c]			
De novo	475/767	1	–
AA	32/54	1.40	0.94–2.08, $p = 0.10$
Lymphoma	47/56	1.12	0.79–1.59, $p = 0.53$
Solid tumors	38/57	1.54	1.08–2.20, $p = 0.02$
Autoimmune disorders	17/20	1.80	1.10–2.95, $p = 0.02$
Year of HCT[d]	–	0.96	0.94–0.97, $p < .00001$
Age at HCT[d]	–	1.20	1.12–1.28, $p < 0.0001$
Platelet count[d]	–	0.93	0.89–0.97, $p = 0.0003$

[a] 21 patients with unknown FAB/WHO classification.

[b] 13 patients in category "very good" not shown; 57 with unknown cytogenetics.

[c] 9 patients with myeloproliferative neoplasms, 8 with constitutional marrow failure syndromes, 5 with multiple myeloma, 4 with organ transplant, 2 with accidental radiation, and 17 with other forms of leukemia not shown; 8 with unknown etiology.

[d] Modeled as continuous linear variable; hazard ratio for year of HCT represents the increase in hazard of death associated with each increase in 1 year; hazard ratio for patient age represents the increase in hazard of death associated with each increase in age of one decade; hazard ratio for platelet count represents the increase in hazard of death associated with each increase in platelets of 50,000.

Multiple comparisons

The issue of multiple comparisons is concerned with the fact that the more often one looks for a difference, the more likely one is to find one that is due to chance alone. If one conducts 100 independent comparisons where there is no true difference between any of the groups being compared, one would expect roughly five of the 100 to lead to a statistically significant (at the significance level of 0.05) difference, i.e. a false positive. This is simply a product of how the Type I error rate is defined. Because of this, however, one must be careful about how one interprets results in which a large number of comparisons are made, as the chance of a false positive increases as more comparisons are made. As a simple example, suppose that one declares a coin to be biased if it comes up heads nine or more times in 10 flips. The probability of this occurring under the null hypothesis that the coin is fair (i.e. the probability of a head is 0.5) is, within rounding, 0.0107. This is, therefore, a relatively rare event under the null hypothesis, and if it were to occur, the null hypothesis should be rejected, that is, one would conclude that the coin is biased. If one were to flip 100 fair coins, the probability of any individual coin being declared fair (eight or fewer heads by our definition) is 1 – 0.0107. However, the probability that all 100 coins are declared fair is $(1 - 0.0107)^{100} = 0.34$. Therefore, with 100 fair coins it would be more likely to conclude incorrectly that at least one coin was biased than it would be to conclude correctly that all 100 coins were fair.

There is a large literature on how to adjust p-values for multiple comparisons [29–32]. One approach is to adjust each comparison (and the resulting p-value) so that the overall Type I error rate is 5% (doing so is called controlling the family-wise error rate). In other words, if there is no difference across any of the comparisons being made, then the probability of falsely concluding that at least one of the comparisons is consistent with a true difference is 5%. The simplest approach to control the family-wise error rate is called the Bonferroni correction, where one simply divides each individual p-value by the total number of comparisons. This can be overly conservative if there is even a modest degree of correlation between comparisons, however. For example, suppose one is comparing overall mortality, non-relapse mortality, grades 2–4 acute GVHD, grades 3–4 acute GVHD, chronic GVHD, relapse, relapse-free survival, time to neutrophil recovery, time to platelet recovery, and occurrence of Gram-negative infection between two groups. This totals to 10 comparisons, but clearly these outcomes are correlated and defining statistical significance as 0.05/10 = 0.005, while maintaining the overall Type 1 error rate of 5%, would also lead to an increase in the false-negative rate (i.e. falsely concluding that there is not a difference when there truly is). If two groups are being compared in a randomized phase III clinical trial, then one single end-point should be chosen (see the discussion later in this chapter).

Another approach to multiple comparisons is to control what is called the false discovery rate (FDR) [33]. This approach is particularly useful when a study is considered more exploratory as opposed to the goal being to define definitive differences. The FDR is defined as the expected proportion of false positives among all tests that are significant at the nominal significance level (typically taken to be 0.05). This approach is commonly taken in large-scale studies such as genomic studies, where one might be assessing the association of thousands of genes with outcome.

Clinical trial design in HCT research

In human subject research, confirmed randomized controlled clinical (intervention) trials provide the most compelling and generalizable evidence of an experimental treatment's effectiveness; observational (non-intervention) studies, although informative, are less compelling. Green and Byar [34] suggested that there is a "hierarchy of study designs," from the least convincing (anecdotal case reports) to the more convincing clinical trial (Table 27.2).

While the scientific question to be addressed by the clinical trial largely dictates the structure of the proposed study, prior to FDA approval, or expanded use of a new therapeutic intervention, a single- or multiple-drug regimen must proceed successfully through the phases of clinical trial investigation, including phase 0, a relatively recent trial classification from the FDA:

Phase 0: Evaluation of biological activity; active experimental therapies proceed to phase I.
Phase I: Evaluation of safety and declaration of maximum tolerated dose; safe/tolerable dose proceeds to phase II.
Phase II: Evaluation of effectiveness; experimental therapies that appear more effective than the standard therapy proceed to phase III.
Phase III: Comparison against the standard; therapies shown to be more effective than the standard therapy proceed to phase IV. Note: FDA approval is typically sought at the completion of a successful phase III study.
Phase IV: Evaluation of effects post-marketing; effect intended to hold in the expanded patient population.

Before a clinical trial can be conducted, many regulatory requirements must be satisfied; a comprehensive overview can be found in a book by Bankert and Amdur [35].

Table 27.2 Hierarchy of strength of evidence concerning efficacy of treatment

Phase 0 clinical trials

A "phase 0 clinical trial" is a term used to reference early phase I clinical trials. Phase 0 clinical trials are considered exploratory; designed to assess an agent's ability to "hit" its intended target and to provide investigators with a deeper understanding of the pharmacokinetics/pharmacodynamics of the agent or therapy. In phase 0 clinical trials, the agent is often given in small (sub-therapeutic) doses, typically single administration at minimal doses. Because the goal of such studies is to evaluate whether or not the proposed agent or therapy shows promise based on the agent's ability to reach the tumor, in most cases there is very little chance that a patient will benefit from participation. Phase 0 studies are intended to observe biologic effects, effects that could not be attributed to chance alone, thereby demonstrating sufficient potential to pursue further studies. While the use and application of phase 0 designs remain the subject of ongoing debate, discussions regarding the risk–benefit ratio and related ethics of phase 0 studies are often contentious; in 2006, the National Cancer Institute started its phase 0 program, based on FDA guidelines [36,37]. The details of the statistical considerations of such small sample calculations were described in Kummar et al. [36], but like most statistical methods, it is based simply on detecting an effect that would not reasonably be ascribed to chance alone. Theoretically, even a single patient can be sufficient where the observation could never have happened spontaneously; nevertheless, most phase 0 studies typically use 3–15 patients.

Phase I clinical trials

These trials are often first-in-human experiments and are concerned primarily with safety, not efficacy. By their nature, early-phase clinical trials tend to include higher risk patients within a certain age group, with particular clinical and disease characteristics, who typically have not responded well to the clinically indicated/available therapies. Such studies are relatively small, usually requiring no more than 40–50 (and often far fewer) evaluable patients. In many instances, the primary objective of a phase I trial is to determine an appropriate dose of the drug being tested, that is, how much drug can be given without causing undue rates of adverse events. This dose is often referred to as the maximum tolerated dose (MTD), and the MTD is defined as the dose that is associated with a specified true target toxicity [or dose-limiting toxicity (DLT)] rate. In oncology, it is commonly assumed that higher doses of drug lead to increased efficacy, but at the potential expense of added toxicity. Identifying the "correct dose" then becomes a balancing act between finding a dose that is high enough to provide sufficient efficacy, yet not so high that toxicity will outweigh the benefits in efficacy. The design of such a dose-finding study requires specification of this target toxicity rate, and also an unambiguous definition of what constitutes a DLT. Since the definition of the MTD involves the target toxicity rate, failure to specify this renders the dose-finding algorithm uninterpretable. In recent years, phase I designs have benefited from a higher degree of statistical rigor. We present here a few of the more commonly used methods for estimating the MTD. In all approaches, it is assumed that there is a range of dose levels to be (potentially) tested.

On occasion, phase I testing is divided into two steps known as phase Ia and phase Ib. Phase Ia studies normally are conducted as a short-term investigation to ensure safety, tolerability, and feasibility in a limited number of patients before embarking on the longer and more comprehensive phase Ib study. Additional patients are usually then treated during the expansion phase (phase Ib) of the ongoing phase I study. The objectives of the phase Ib study are to assess and characterize further the safety profile, pharmacokinetics, and pharmacodynamics of the investigational agent across multiple dose levels.

3 + 3 design

Probably the most commonly used (yet the least statistically rigorous) method, this approach works well if the target toxicity rate is on the order of 33%. The 3 + 3 design is not, however, a "one-size-fits-all" approach for dose-finding studies. This design dictates that patients are treated in cohorts of three. If no DLTs are observed in a cohort, the next group is treated at the next higher dose level. If two or more DLTs are observed, the next cohort is treated at the next lower dose level (and typically this dose level is never returned to). If one DLT occurs in a cohort, the next cohort is treated at the same level. If one additional DLT is observed (for a total of two of six), then this dose is identified as the MTD. If no additional DLTs are observed (for a total of one of six), the next cohort is treated at the next higher dose level. If two or more additional DLTs occur, then the next lower dose level is identified as the MTD.

There are many variations on this basic design, including identifying the MTD as the dose where one of six DLTs occur or just below the dose in which two of six DLTs occur. If this variation is used, then one should be using a target toxicity rate on the order of 15–20%.

Storer's two-stage design

One feature of this design is that it allows the possibility to move more rapidly through lower dose levels, thereby increasing the chance that fewer patients are treated at lower doses that are presumably less efficacious [38]. The design also more directly (relative to the 3 + 3 design) estimates the dose that is associated with the target DLT rate. In particular, in the first stage, single patients are treated at increasing dose levels until a DLT is observed. At this point, the second stage begins at the next lower dose level. In the second stage, a number of patients are treated in cohorts of a specified size with rules similar to those from the 3 + 3 design. The cohort size is chosen to reflect the target toxicity rate. For example, if the target is around 30%, a reasonable cohort size is three; if the target toxicity rate is 20%, a reasonable cohort size is five. This approach is continued until a specified number of patients have been treated in the second stage, at which point a dose–toxicity curve is fit to the observed data. From this fitted curve, the dose that is associated with the target toxicity rate is then taken to be the estimated MTD. The fitted dose–toxicity curve could theoretically take any form, but typically it is assumed to be a two-parameter logistic model.

Continual reassessment method

This is a Bayesian approach in which the design is adapted based on information gained as the trial progresses [39]. As with any dose-finding study, the design requires specification of a target DLT rate. A "prior" dose–toxicity distribution is assumed based on previous experience. Then a single patient or a cohort of patients is treated at the dose that, based on the investigator's best guess, is associated with the target toxicity rate. Based on the observed data, the dose–toxicity curve is then updated, and the next patient or group of patients is treated at the dose that is associated with the target DLT rate from the updated dose–toxicity distribution. This process is continued until either a specified number of patients are treated or until some level of precision is met. Some modifications of the continual reassessment method (CRM) have been proposed so that escalation cannot increase too rapidly and so that there is less dependence placed on the assumption of the prior distribution.

Bayesian design (considering toxicity and efficacy simultaneously)

Some dose-finding designs consider not only toxicity, but the dose modification is also based on efficacy [40]. This is only feasible if efficacy is a relatively short-term end-point, e.g. early response, acute GVHD, graft failure. This particular design seeks to balance the possibility of increased efficacy with higher dose levels with the downside of increased toxicity at the higher levels. A minimum acceptable efficacy rate is specified along with a maximum acceptable toxicity rate, and the design seeks to find a dose where the efficacy rate exceeds this level while at the same time having a DLT rate lower than the maximum acceptable rate. While such a design examines efficacy, it only does so to help identify the best dose to take forward. Once such a dose has been identified, it has not necessarily been proven to be potentially efficacious as is the goal in a phase II study (see below).

These are just a few of many possible phase I designs, leading to the question of which method one should use. Storer undertook an extensive simulation study to compare the operating characteristics of several different methods under a wide variety of assumed-true scenarios [41]. If one tailors the appropriate method to match the target toxicity rate, many of the methods that were examined led to acceptable operating characteristics. When designing a dose-finding phase I study, it is advisable to examine the operating characteristics of the design to ensure that one has a reasonably high probability of getting an acceptable answer.

Phase II clinical trials

Once one has completed a phase I trial and identified a dose to be taken forward, the next step is to conduct a phase II trial, where the primary objective is to examine potential efficacy. Such trials are typically larger than phase I trials but in the field of HCT rarely enroll more than 80–100 patients. As with phase I trials, there is a variety of phase II designs. We highlight here the salient features of some of the more common designs; more details in addition to other designs can be found elsewhere [42–48].

Single-arm trial: comparison with fixed outcome from historical controls

This is the most common and simplest phase II design. If one has a situation where there are reliable historical data that one hopes to improve upon with the treatment under study, then using traditional methods one can power a study to show a statistically significantly improved outcome over the fixed historical rate. The assumed-true outcome for the experimental treatment can come from preliminary data or from a desired level that, if not achieved, would generate little enthusiasm for continued study. The null hypothesis (assuming a binary outcome, which is common for phase II trials) is then set up as H_0: $p = p_0$ and the alternative hypothesis as H_1: $p = p_1$, where p is the true "success" rate, p_0 is the fixed rate that one wishes to improve upon, and p_1 is the assumed-true rate for the treatment under study. It is important to note that in such a study, the historical rate is treated as fixed, hence the statistical test is a one-sample test.

Frequently, single-arm studies are conducted in two stages so that if there is not sufficient evidence of potential efficacy in the first stage, the trial is terminated early. There are multiple specific approaches to this, the difference in approaches essentially being based on how one defines lack of sufficient evidence of efficacy. One of the most common approaches is known as the Simon optimal design [42]. This approach chooses the size of the first stage, the size of the second stage, the number of "successes" in the first stage required to proceed to the second stage, and the total number of successes (in stages one and two) required to deem the regimen under study as potentially efficacious for a specified significance level, power, response rate under the null hypothesis, and assumed-true response rate under the alternative hypothesis. These parameters are chosen so that the expected sample size (under the significance level and power) is minimized.

As an example, suppose one is testing a regimen intended to decrease the probability of acute GVHD, where historical data indicate a probability of 70% among patients consistent with the eligibility criteria for the trial being designed. If the assumed-true GVHD rate is 50% for the experimental treatment, then with 90% power and a 5% significance level, the Simon optimal design dictates that if 16 or more cases of GVHD occur in the first 24 patients, the trial should be terminated owing to lack of efficacy. If 15 or fewer cases occur, then an additional 39 patients are to be enrolled for a total of 63. If 38 or fewer cases of GVHD occur among the 63 patients, then the drug is regarded as being potentially efficacious. The expected sample size of such a design if the true GVHD rate is 70% is 34.7 patients. Note that the design specifies that the observed sample size is either 24 or 63, and the expected sample size is therefore simply a combination of 24 and 63. In this example, the probability of 16 or more cases of GVHD (the trigger for early termination) among 24 patient under the null hypothesis 0.725, so the expected sample size is $(0.725 \times 24) + [(1 - 0.725) \times 63] = 34.7$.

Randomized phase II clinical trials

In recent years, there has been increasing debate regarding the most appropriate use of randomized designs for phase II studies in HCT. Because efficacy end-points in a single-arm phase II trial can be impacted by differences in patient selection, disease/disease status, type/extent of prior treatment(s), and changes in supportive care, outcomes can vary between the experimental and the historical/reference patient groups. The introduction of these potential biases makes definitive conclusions regarding improvement in outcome problematic. Findings from simulation studies performed by Tang et al. showed that a historical estimate of success that is misspecified by as little as 5% can triple the false-positive rate in an uncontrolled trial [49,50]. Although a case can be made for randomization in place of a single-arm phase II trial, more often than not the expense – both human and financial – associated with the formal comparison of outcomes between different treatment groups can make the pursuit prohibitive.

In general, there is agreement that one of the best uses of the randomized phase II design is in the context of evaluating multiple treatment regimens (≥2), where the primary objective is to select the "better performer." This type of design is referred to as the "phase II selection design" and is not powered to test for differences between treatment arms, rather a comparison of performance [51]. Under the selection design, patients are randomized to one of two or more treatments; each treatment must show some prespecified benefit at the end of the first stage (e.g. percentage decrease in relapse/progression rate) to proceed to the second stage. The time required to enroll, treat, and assess patients for the outcome of interest is intended to be short, both by evaluating after a relatively small number of patients and also by utilizing end-points that are reached early and where the minimal clinically relevant difference is relatively large [51]. Because the emphasis is on selecting the best performer from a group of promising experimental regimens, standard of care or control arms are not typically included.

Phase III clinical trials

If a treatment is found to be potentially efficacious in a phase II trial, then generally the experimental therapy is tested within a phase III trial against either a placebo or the standard treatment for the indication for which the treatment is being given. Typically, the comparison of treatment arms is done based on a single primary end-point, and a difference, or lack thereof, in this end-point is what dictates whether or not the two arms are deemed as being truly different. A single primary end-point is chosen to avoid the issues of multiple comparisons as detailed above. A phase III trial requires a very high level of detail in the written protocol, from the points of view of both planning and implementation and also the planned statistical analysis of the observed data. A well-designed phase III clinical trial is necessary to provide scientific proof of efficacy of the treatment under investigation. In fact, if FDA approval for a drug or approval for a particular indication is being sought, typically two positive phase III trials are required. There are several important components that contribute to a phase III clinical trial, outlined below.

Randomization

The primary rationale for randomization in a phase III trial is the desire to balance the treatment arms with respect to factors known (or unknown) to influence the outcome so that an unbiased comparison between arms can be made. Ideally, one hopes that, on average, the only attribute that separates the arms is the treatment, and therefore any differences observed in outcome can be ascribed to the treatment, where the observed difference is assessed relative to differences expected due to chance alone.

Randomization should only occur after it has been determined that a patient is eligible for study and has consented. It is also desirable to randomize as close to possible to the administration of the treatment arms to avoid patients dropping out without receiving the treatment to which they were randomized. The actual randomization process can be done in any number of ways. It is relatively common to conduct the randomization in "blocks" of a certain size (typically a multiple of the number of arms), such as 4–8 patients, so that at the end of enrollment of each block the number of patients in each arm is the same. Block sizes are generally varied randomly and the size is not specified in the protocol. Another approach to ensure that the number of patients randomized to each arm is roughly the same is adaptive randomization [52]. If imbalance begins to occur between arms, subsequent patients are randomized to the arm with fewer patients with a probability higher than 0.5. This is continued until some specified level of balance is achieved.

Although randomization is conducted to minimize the chance of bias (i.e. one arm having a higher proportion of high-risk patients than the other arm), considerable variation in prognosis can lead to a non-negligible chance of this still occurring. Because of this, the randomization is often stratified, where patients are divided into groups, or strata, based on factors that are known to have a major influence on the outcome. Some examples of common strata for HCT trials include age, disease status, and type of donor. Randomization is then typically conducted within each stratum. One must be careful in such instances not to stratify for too many factors, as the number of strata increases rapidly with additional factors, and some strata are then likely to have relatively few patients enrolled. This can lead to an imbalance in the number of patients randomized to each arm. Typically, stratification is limited to 2–4 factors if possible, although this number certainly depends on the particular factors, the number of patients expected within the various strata, and on the total number of patients to be randomized.

If a patient is randomized, regardless of whether that patient receives the treatment to which they were randomized, they need to be analyzed based on their randomized treatment. This is known as the intent-to-treat principle. The primary analysis in a phase III clinical trial is done on an intent-to-treat basis, as patients who go on to receive a treatment to which they were not randomized could have done so for reasons that can have an influence on the primary end-point. The notion of intent-to-treat is relevant only to randomized trials, although the term is frequently used (inappropriately) is the non-randomized setting. For further discussion on the intent-to-treat principle, see [5,53].

Sample size

One of the most important features of a phase III clinical trial is specification of the sample size. The number of patients to be enrolled needs to be large enough that if meaningful differences are observed, it can be concluded with high probability that such a difference is real and not due to chance alone. On the other hand, phase III trials often are constrained by the number of patients available to be enrolled, and therefore a sample size that is larger than necessary also is not desirable (admittedly, this is a problem that rarely occurs in HCT). The methods used to calculate a sample size are dependent on the primary end-point. The primary end-point can almost always be categorized as being associated with one of three types of outcome: binary, continuous, or time-to-event. In order to calculate the required sample size, one must specify the assumed-true probability of success, value, or rate in each arm. Depending on the outcome, some specification of the variance is also required (depending on the type of outcome, this may or may not need to be explicitly stated). One can either estimate the power to observe a statistically significant difference given the assumed-true parameters, or one can estimate the number of patients required to have a specified power to observe a statistically significant difference. The power (or sample size) is then essentially a function of the assumed-true difference in the outcome divided by the standard error of the difference, with factors included that represent the sample size (or power) and the significance level.

If the outcome is time-to-event, then sample sizes are not as straightforward as for binary or continuous outcomes, as there are many more assumptions that go into the calculation. For time-to-event outcomes, the required sample size decreases as the failure rate increases when the relative difference between groups is the same. For example, if the failure rates are 90% and 45% (twice as high in one group) relative to 30% and 15%, the former case will require fewer patients to attain the same level of power relative to the latter case. In other words, power for time-to-event end-points increases as the number of events increases. Formulas for power exist for such end-points, but they require fairly restrictive assumptions [54]. One particularly flexible method to estimate power for time-to-event end-points is to fit a "piecewise exponential model" to the observed data for the standard or control arm, in addition to the experimental arm, that lead to the phase III trial. If the hazard of failure is constant, then the time-to-event distribution follows an exponential model. One can therefore break the time axis into mutually exclusive and exhaustive windows, within each of which it is assumed that the hazard of failure is constant. In most cases, specification of as few as 5–10 windows can lead to assumed-true time-to-event distributions that closely fit the observed data. From these distributions, one can then randomly generate observed outcomes for a specified number of patients, thereby generating simulated outcomes from a simulated clinical trial. The outcomes for the two groups can then be compared with the appropriate test statistic that is specified for the phase III trial (e.g. the log-rank test), thereby generating a p-value for each simulated trial. This can be done over and over many times, and the proportion of trials in which the p-value is less than the significance level (typically 0.05) represents an estimate of the power of the trial given the specified sample size, significance level, and assumed-true time-to-event distributions.

As an example, consider the data shown in Figure 27.5, where the step function (in black) represents the observed progression-free survival (PFS) for a "standard" therapy group (i.e. the KM estimate). Superimposed on this observed outcome is a piecewise exponential model, where it is assumed that the hazard of relapse or death is constant within each of several windows (but different across these windows). As can be seen, this assumed-true curve nicely fits the observed data. One can then assume that the true hazard of relapse or death for the experimental arm is a constant factor less than that for the standard arm (i.e. that the hazards are proportional), leading to the assumed-true PFS distributions shown for two potential hazard ratios (where the hazard ratio represents the hazard of failure in the standard arm relative to the experimental arm).

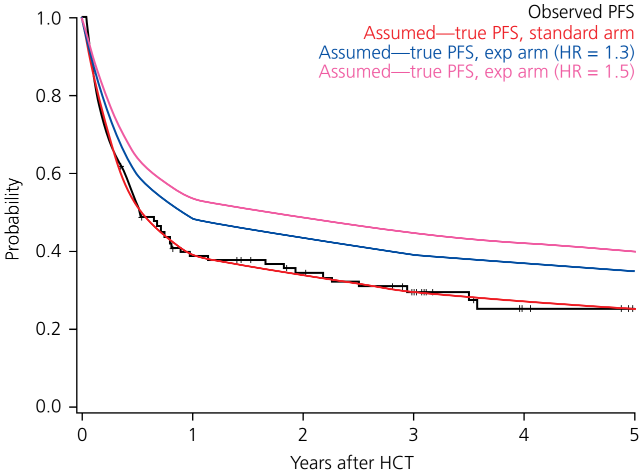

Figure 27.5 Piecewise exponential progression-free survival fit to observed data (assumed-true PFS, standard arm) with assumed-true PFS for two hypothetical experimental arms. (For a color version of this figure, please see the color plate section.)

Once these assumed-true distributions are specified, one can randomly draw PFS times for a specified number of (simulated) patients for each group, thereby generating a simulated clinical trial and its corresponding *p*-value. Since power for time-to-event end-points depends on the number of events, in order to generate PFS times randomly for a specified number of patients one must assume an enrollment period and a minimum follow-up time. Suppose we assume a 3-year enrollment period in the current example with a minimum of 2 years of follow-up. Randomly generating 5000 simulated trials based on the above with 200 patients per group yield an estimated power of 90% (and an average of 255 events) for the case where the hazard ratio HR = 1.5 and 57% power (and an average of 265 events) for the case where HR = 1.3.

Interim analyses

Most phase III trials examine the outcome between groups at least once at some point before all patients have been accrued. If one group is performing dramatically better than the other, then it is not ethical to deny future patients the treatment that is clearly better. On the other hand, if it is extremely unlikely that completion of the trial will lead to a statistically significant difference given the results thus far observed, continuation of the trial may not be worth the effort and expense since the answer (with respect to the primary end-point) is already almost certainly known. The examination of the data before the trial is complete is called an interim analysis. Care must be taken with how interim analyses are conducted, however, owing to the issue of multiple comparisons discussed above. In other words, the more often one examines the data, the more likely one is to see a difference due to chance alone. Moreover, multiple looks at the data lead to a larger significance level at the end of the completion of the trial than what was used to design the study. In order to maintain the overall level of significance at the level specified (usually 0.05), the interim looks require a lower level of significance to stop the trial early. There are many ways to specify the significance levels of the interim looks [5], but all are consistent with the notion that the more interim looks, the lower is the significance level of each. Some approaches also utilize lower significance levels when the interim looks are earlier in the trial and higher significance levels (but still below 0.05) closer to the end of the trial.

Adaptive designs

Recently, adaptive designs for phase III trials have become more popular. In such designs, patients are not necessarily randomized 50:50 as they enter the trial; rather, a particular patient is more likely to receive the treatment that has, on average, had the better outcome up to that point. Such designs are Bayesian, and some feel that they are more ethical. They are not, however, without controversy. Several references contain excellent discussion on the issues, both favorable and unfavorable, of adaptive designs [55–57].

Interpreting the results of phase III trials

As noted above, phase III trials generally should have a single primary end-point, upon which the sample size of the trial and conclusions, for the most part, are based. All trials have secondary end-points that are specified in the protocol, but if the treatment groups are not statistically significantly different for the primary end-point, differences in the secondary end-points at the nominal significance level of 0.05 need to be viewed with caution, again due to multiple comparisons. It is also common to see subgroup analyses conducted at the end of a phase III trial. Such analyses should be specified in the protocol prior to the start of the study, and the significance of such analyses must take into account the multiple tests that have been conducted.

Observational study designs

Although clinical trials are the most scientifically valid method of addressing a clinical hypothesis, they require substantial patient and financial resources, particularly phase III clinical trials, and such resources simply do not exist to answer all questions of interest. Moreover, it is often the case that it would be unethical or not possible to test a particular hypothesis in a randomized clinical trial. For example, suppose one wishes to examine if patients mismatched at HLA-DRB1 at the allele level have more GVHD and mortality than those matched at HLA-DRB1 at the allele level among patients who are matched at HLA-A, -B, and -C at the allele level) and at HLA-DR at the antigen level with their unrelated donor. It would not be ethical to randomize patients to be matched or mismatched with their donor. In fact, all advances in the requirement for HLA matching have been attained from observational studies. Researchers should recognize, however, that the statistical analysis of observational studies can often be more difficult than prospective clinical trials because measuring confounding factors can be difficult, costly, or impossible, and some such factors may not even be recognized. In addition to such confounders, observational studies that examine survival end-points can be misleading if follow-up is not standardized. For example, if standard follow-up is planned for 5 years, and passive follow-up occurs subsequently, the survival estimates will be unreliable, as passive follow-up gathers more information on the more-at-risk patients. Despite these limitations, observational studies can prove to be useful alternatives to clinical trials when a prospective trial is not possible. Observational studies can also be used as a prelude to and motivation for conducting a randomized phase III trial. We discuss below three types of observational studies.

Retrospective cohort study

This is the most common type of observational study performed in the field of HCT. Part of its popularity is due to the existence of large amounts of data from transplants that have already been conducted, either within single institutions or from registry data through organizations such as the Center for International Blood and Marrow Transplant Research (CIBMTR) and the European Group for Blood and Marrow Transplantation (EBMT). Similarly to a clinical trial, an observational study is aimed at answering a particular question among a specified group of patients. Many of the statistical methods used to analyze data from a clinical trial are also appropriate in a retrospective study, although regression analysis is the bread-and-butter tool in such studies. Since patients have not been randomized or accrued based on some list of eligibility criteria, there is a much larger chance of selection bias and unequal distribution of risk factors in retrospective studies. Regression analysis is therefore commonly used to account for these imbalances. The objective of a retrospective cohort study can be broadly categorized as one of three goals: one might be interested in comparing outcomes between groups A and B; one might be interested in testing the impact of a particular variable on outcome; or one might be interested in identifying risk factors for a particular outcome. Note that the last two objectives could be done in the context of a randomized clinical trial, but this would be done after the trial has been completed and would not have been the primary objective (or likely even a secondary objective) of the clinical trial. Therefore, even though the data may have come from a randomized trial, the conclusions from the retrospective study would not carry the same scientific validity as those from the clinical trial.

Given that this type of study is retrospective, patients have already been treated and outcomes observed, and one has no control over factors that were measured as the data have already been collected. If the objective of the study is to compare outcome between two groups or to examine the association of a particular factor with outcome, the appropriate regression technique is employed (based on the type of outcome) and every effort is made to control for factors that may influence outcome so that the observed difference between groups can be attributed to the groups alone or so that the association of the factor examined is not explained by other factors. If the goal is to identify risk factors for an outcome, stepwise regression techniques are typically used. As discussed above, care must be taken in the number of factors that one includes in the regression model, and one also needs to consider the effect of multiple comparisons.

When comparing the outcome between two groups in this sort of study, investigators often wish to impose balance by matching for certain factors, leading to a so-called matched-cohort design. In our experience, we feel that this is often driven by the misplaced desire to obtain two groups that are roughly similar, that is, to mimic a randomized clinical trial. However, if all data for "eligible" patients are available, we prefer to use all patients and then use regression techniques to control for potential imbalances. This will increase the power to see a difference (since the sample size is maximized) and obviates the need for some sort of selection process in the matching of patients. We also frequently see a matched-cohort design misinterpreted as being a matched case–control study (see below). In a cohort study, patients are not identified based on whether or not they experience some outcome.

Retrospective case–control studies

When the outcome of interest is relatively rare, a retrospective case–control study may be the best design for identifying potential risk factors or comparing two groups. In a case–control study, cases are defined as subjects who fail from the outcome of interest. One or more controls are then chosen for each case, where the controls did not fail from the outcome of interest. The controls are typically matched to the appropriate case for certain factors known to influence outcome. Care must be taken not to overmatch cases and controls on more than a few key factors, owing to the increased difficulty of identifying appropriate matched controls. If failure for the outcome under study can occur reasonably late after HCT, controls should be chosen such that the follow-up time is at least as long as the failure time for the relevant case (this is called a nested case–control design).

Since only a subset of controls (i.e. non-failures) is examined, failure rates cannot be directly estimated in a case–control study. Instead, an odds ratio (OR) is calculated using conditional logistic regression to quantify the difference in outcome between groups that are being compared or to assess risk factors that are being examined for association with failure for the outcome being studied. Like the retrospective cohort study design, case–control studies are subject to uncontrolled variation and potential biases. Matching for various factors helps to reduce this, but the results can certainly be confounded by other factors. As such, adjustment for such factors is often essential in order to obtain a more precise estimate of the true effect being examined.

Prospective cohort study

Of the three types of observational discussed, this is likely the least common. In a prospective cohort study, one identifies a population to study and this group is followed forward in time for the outcome of interest. What makes this type of study different from a clinical trial is that there is no intervention given to the patients being followed. This type of study can be used to estimate the incidence of and risk factors for a particular outcome, and it allows the consistent, accurate collection of data that might not otherwise be available. As with the other types of observational studies discussed, adjustment for factors that might affect the outcome is usually necessary. Because such a study is prospective, long follow-up is often required to observe a sufficient number of events relevant to the outcome under study.

CHAPTER 28

Outcomes Research in Hematopoietic Cell Transplantation

Stephanie J. Lee
Fred Hutchinson Cancer Research Center and University of Washington, Seattle, WA, USA

Introduction

The field of hematopoietic cell transplantation (HCT) has grown dramatically since the first successful allogeneic transplant procedure was performed in 1968. However, as the subspecialty has matured, questions about costs and cost-effectiveness, quality of life (QOL), patient preferences, medical decision-making, and aggregation of different data sources to guide treatment decisions have become relevant. These questions are best addressed by "outcomes" research, a field of study focused on obtaining the best results, broadly defined, given the available medical knowledge and limited healthcare resources. A closely related discipline, health services research, is concerned with social and political determinants of outcome such as access to healthcare and quality of care [1].

There are several features of HCT that make outcomes studies especially relevant: (i) HCT involves high treatment-related risks compared with other medical interventions; (ii) significant practice variation exists; (iii) costs are high; and (iv) the long-term results, considering both disease-free survival (DFS) and QOL, have much room for improvement. On the other hand, several characteristics of HCT make outcomes studies challenging. For example, HCT patients are often not represented in large, administrative databases that collect population-based clinical, outcome, and resource utilization data. The most active transplant centers perform only a few hundred procedures per year, and smaller centers may do fewer than 10. Thus, the overall impact of HCT on the health of the general population and healthcare finances is still relatively small. Also, HCT is changing rapidly, and adequate information on long-term results lags the innovation in the field.

This chapter presents a brief history of outcomes research in American medicine to help frame the research topics and methods. The remainder of the chapter is organized around several specific questions in HCT that outcomes research is well suited to answer. Representative HCT studies are used whenever possible to illustrate the principles discussed. Readers are referred to Chapter 27 (Biostatistical Methods in HCT), Chapter 33 (Assessment of Quality of Life in HCT Recipients) and Chapter 37 (Bone Marrow and Peripheral Blood Cell Donors and Donor Registries) for detailed information on related research methods and data sources.

Definition

It is difficult to state a precise definition of "outcomes research." At some level, all results can be considered outcomes; thus, most scientific investigation is concerned with measurement and interpretation of outcomes. However, phase I, II and III clinical studies addressing efficacy questions are generally excluded from the definition of "outcomes research" when the primary end-points are toxicity, disease control, and survival. Similarly excluded are clinical epidemiology studies that describe an institutional experience with a disease or treatment. However, when the research question begins to consider how well a treatment works outside a clinical trial or institutional setting ("effectiveness"), subjective end-points (e.g. QOL, patient preferences), non-biologic influences on outcomes (e.g. access, quality of care, physician–patient communication, medical decision-making), healthcare policy (e.g. economic evaluation), or aggregation of data from multiple sources (e.g. decision analysis, meta-analysis, use of administrative databases or registry data), then the title "outcomes research" is appropriate. A conceptual framework that distinguishes outcomes research from other types of clinical research is presented in Figure 28.1 [1].

Major questions for outcomes research in HCT include the following:

- What are the costs of HCT and how can they be reduced? (Resource utilization, cost minimization.)
- Are the clinical benefits of HCT worth the monetary cost? (Cost–benefit, cost-effectiveness, cost–utility analysis.)
- What is the patient's experience with HCT? (Qualitative research, QOL, development of patient-reported measures.)
- How can one combine information from several different data sources? (Registry studies, decision analysis, meta-analysis, evidence-based medicine.)
- How can the practice of HCT be improved through health services research? (Access, quality of care, practice variation.)

History

The ultimate goal of outcomes research is to improve the practice of medicine through the provision of data about the effectiveness, costs, risks, and benefits of treatment options, incorporating both individual and societal level considerations. In 2012, the term "comparative effectiveness" was promoted to encompass information on the effectiveness, risks, and benefits of treatments. Hundreds of millions of dollars in research funding are being disbursed through the Patient-Centered Outcomes Research Institute (PCORI), a private, non-profit oversight committee created by the Affordable Care

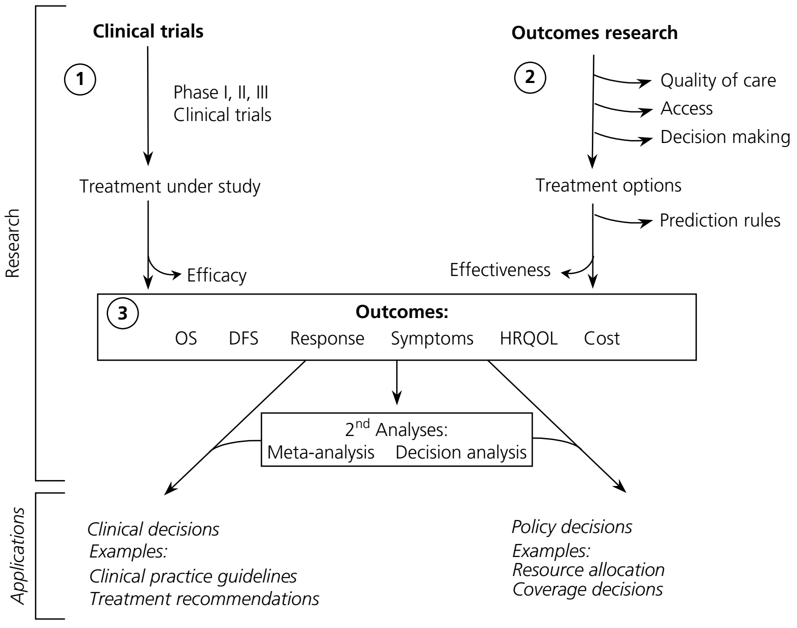

Figure 28.1 Conceptual framework. Interaction is shown between research topics, end-points, analytic techniques, and applications in defining outcomes research. In **1** are depicted the classical clinical trials and analytic techniques that are not outcomes research. Item **2** shows the study topics, end-points, and analytic techniques that are considered to be outcomes research. Outcomes depicted in **3** may or may not constitute outcomes research, depending on the context. For example, overall survival as measured in a phase III trial is not an outcomes study (efficacy), whereas it is if observed in a large community cohort (effectiveness). Symptoms have both efficacy and outcomes influences. Applications are indicated in *italics* and may emanate from either clinical trials or outcomes research. DFS, disease-free survival; HRQOL, health-related quality-of-life; OS, overall survival. Source: Lee et al. 2000 [1]. Reproduced with permission of Oxford University Press.

Act legislation. But approaches to achieve this goal in the United States have been ongoing for a century, influenced by the social and political environment.

The "father" of the American outcomes movement was a surgeon named Ernst Codman. As early as 1914 he argued that the quality of hospitals could be judged only if procedure success rates were made available on a routine basis [2]. He advocated standardized measures of outcomes so that different institutions could be compared on a level playing field. In 1966, Avides Donabedian reintroduced the term "outcomes" when he developed his concept of quality assessment and its three components: *structure*, *process*, and *outcome*. He broadened the end-points of interest: "Although some outcomes are generally unmistakable and easy to measure (death, for example), other outcomes, not so clearly defined, can be difficult to measure. These include patient attitudes and satisfactions, social restoration, and physical disability, and rehabilitation" [3].

In the 1970s and 1980s, the looming crisis of healthcare costs pushed outcomes research into the political spotlight. Archie Cochrane, after whom the Cochrane evidence-based database is named, warned that the medical system would become bankrupt if expensive technologies were routinely applied without evidence of benefit [4]. In 1973, Wennberg and Gittelsohn documented surprising geographic variations in resource utilization, expenditures, and rates of hospitalization and procedures without differences in outcomes [5]. This observation focused attention on practice variation and the possible cost savings that could be realized by eliminating unnecessary procedures.

Several national databases were established to study practice variation in the United States. These included the National Cancer Data Base (focusing on surgical practice) and the linkage of Medicare billing and Surveillance, Epidemiology and End Results (SEER) data (providing resource utilization and cancer-specific information on patients common to these databases). In addition, the Federal government established the Agency for Health Care Research and Quality (AHRQ) to support outcomes research. Although this organization has been renamed and refocused several times, it is probably most famous for developing the Patient Outcomes Assessment Research Teams (PORTs) in the 1990s. The PORT program was designed to determine the relative effectiveness of treatments for common diseases, with an undertone of trying to standardize clinical practice.

The 1990s were a period of national economic growth in the United States, and concerns about healthcare financing for specific procedures faded into the background behind debate about the overall structure of healthcare coverage. Managed care and health maintenance organizations thrived, and physicians practiced in a more constrained setting with new concerns about financial risk. The incentive to save money may have replaced the original goal of outcomes research, which is to spend money wisely to improve overall health. As it became clear that the Clinton administration's major restructuring of healthcare delivery and financing would fail, outcomes research faded from the political spotlight and returned to its origins, focusing on more applied questions. Treatment guidelines proliferated in the late 1990s, but these efforts grew out of a desire to standardize physician practice and improve patient outcomes rather than to contain costs.

In 2000–2001 the technology bubble popped and in 2007–2008 the housing and credit debacles plunged the country into financial crisis. President Obama signed the American Recovery and Reinvestment Act of 2009, which included \$1.1 billion dollars for comparative effectiveness research, to be overseen by the Federal Coordinating Council. However, the Patient Protection and Affordable Care Act of 2010 superseded the previous funding and structure, and created PCORI. In 2012, the US Supreme Court upheld the constitutionality of the Affordable Care Act by a 5–4 margin.

It is difficult to tell what the future holds for outcomes/comparative effectiveness research, especially in HCT. HCT is a highly specialized practice that for many will fall outside healthcare policy and economic considerations. Nevertheless, there are many aspects of HCT that may make outcomes research more relevant. Attention to long-term outcomes, patient decision-making, and guidance based on what is known about short-term outcomes is especially critical for the field.

Specific questions for the field of HCT

What are the costs of HCT, and how can they be reduced?

On a per patient basis, the costs of HCT are high relative to other available medical interventions, ranging from approximately $70,000 for an uncomplicated autologous procedure to $200,000 for an allogeneic, myeloablative procedure using an unrelated donor [6,7]. According to AHRQ, HCT is one of the 10 medical procedures with the fastest rate of cost increases due to both increasing hospital days and costs of hospitalization [8]. The investment in infrastructure is immense, requiring support of the transplant centers and national resources such as the National Marrow Donor Program and the public cord blood banks. In the United States, private and public payers have tried to limit access to some HCT procedures, but are often forced by state law, threat of patient lawsuits, or public opinion to acquiesce and provide coverage for the procedures.

Well-established research methods are available for quantifying monetary costs [9–11]. “Direct medical” cost refers to the monetary value of goods and services provided. These costs are usually captured through administrative billing systems or other itemized methods of determining resource utilization. Notably, countries with nationalized healthcare systems often have poorly developed administrative cost databases, making cost research in these countries difficult or impossible. The distinction between “charges” and “costs” is important in the United States. Charges are the amount billed to the patient or insurance company. Costs are usually lower and reflect the actual resources needed to provide a service. Because healthcare organizations offset one expense against another and usually expect some amount of profit, charges are not directly linked to the resources needed to provide a service.

Outcomes studies favor the use of costs since they reflect the actual resources expended. When costs are not available directly, conversion between charges and costs may be determined by “ratios of costs to charges” (RCCs), a fraction recalculated on an annual basis. Institutions often aggregate logical groups such as clinical departments when setting their RCCs. Fixed costs (such as physical space, personnel) and variable costs (supplies) are totaled and divided by the amount billed by the department during the same period of time.

Direct *non-medical* costs are expenditures related to healthcare, but not directly used for goods and services (e.g. transportation to the hospital, hotel charges for family members accompanying patients). These costs have proven much more difficult to quantify since they must be captured directly from patients through cost diaries or receipts. *Indirect* non-medical costs are even harder to quantify and include time off work and the loss of future earnings. Which costs to include in the analysis depends on the desired perspective. The “societal” perspective includes all costs to the system regardless of who pays. Other perspectives can be imagined, such as the hospital, insurance company, or patient, and would include only costs borne by that payer.

One important feature of costs is that they vary by year because of inflation, so costs in different years must be “inflation adjusted” to allow comparability of studies performed at different times (see http://stats.bls.gov). “Discounting” is distinct from inflation adjustment, and is normally set at 3% per annum. Discounting reflects the fact that costs and benefits in the future are valued less than those that are immediately available, and allows conversion of future dollars or future improvements in health to their current value.

Once the relevant costs have been captured, they can be analyzed in a variety of ways. Studies may simply report the costs of an intervention or look for patterns of costs, predictors of costs, or ways to decrease costs. Totals, breakdowns by specific categories, trends over time, and association with clinical characteristics or treatments have all been reported in HCT. For example, several studies have evaluated the costs associated with specific complications or patient characteristics [12,13]. Cost-minimization studies compare the costs of treatment approaches that result in similar clinical patient outcomes. In these cases, adoption of the least costly approach saves money and does not compromise patient outcomes [14–16].

Are the clinical benefits of HCT worth the monetary costs?

Deciding whether the clinical benefits of HCT are worth the monetary costs may seem to conflict with a physician’s duty to their patient. However, in a society where healthcare dollars are constrained, spending money for one person’s procedure ultimately means that another person may not receive some necessary treatment. As discussed below, the various forms of economic analysis (cost–benefit, cost-effectiveness and cost–utility) differ primarily in how they quantify clinical benefits. However, all are trying to provide information that may be used by policy makers to allocate resources and maximize the health and welfare of the entire population.

Cost–benefit analysis requires that clinical benefits be converted into monetary values to determine the net financial impact of an intervention. This is sometimes straightforward (inexpensive prophylactic antibiotics may prevent costly infections later) but is often quite complicated and fraught with unpalatable value judgments. For example, what is the economic value of a life extended or saved? Attempts to use income as a surrogate lead to the uncomfortable conclusion that the lives of high-wage earners are more valuable than those of homemakers or retired people [9]. As a consequence, cost-benefit analysis is rarely performed in healthcare; it is much more common in business and environmental applications.

Cost-effectiveness analysis avoids such value judgments by calculating a “cost/effectiveness ratio” expressed as dollars per unit of clinical benefit [10]. To facilitate comparison across interventions, clinical benefit is usually measured in years of life gained (life-years, or LYs), but may be any clinically recognized unit of benefit [e.g. cases of chronic graft-versus-host disease (GVHD) prevented, days of hospitalization, lives saved]. Cost/effectiveness ratios are by definition comparisons of one treatment approach versus another (which may be “no treatment”) since they are calculated as

$$\text{(cost of treatment X minus cost of treatment Y)} / \text{(benefit of X minus benefit of Y)}$$

Because cost-effectiveness analyses are intended for policy makers, it is important to specify the perspective (e.g. government program, hospital, health plan) and time horizon (e.g. 1 year, 100 years) of the analysis in order to reflect which costs and benefits were included. The strategy that is most cost-effective for a health maintenance organization may not be the one that is most cost-effective from the viewpoint of a hospital, the patient, or society.

Many people use the terms “cost-effectiveness analysis” and “cost–utility analysis” interchangeably. However, a *cost–utility analysis* specifically incorporates QOL considerations and usually has a denominator of quality-adjusted life-years (QALYs) where survival time is adjusted for the QOL associated with that survival. These adjustment factors are called “patient utilities” and usually range from 0 (equivalent to being dead) to 1.0 (the year of life is fully valued). A utility less than 0 represents a health state worse than death. Utilities fulfill the mathematical condition of linearity so that 1 year of perfect health is considered equal in value to 2 years of life with a utility of 0.5. Some quoted patient utilities for health states are 0.98 for suffering the side effects of beta-blockers [17], 0.8 when 1 year after autologous transplantation for non-Hodgkin lymphoma (NHL) [18], and 0.5 following a stroke [19]. Interestingly, the Affordable Care Act specifically prohibits inclusion of utilities that would value the lives of elderly, disabled or terminally ill people less than those of young and healthy people. Empiric data suggest that age is not necessarily associated with worse QOL, and older people often report better QOL than younger people. Conversely, failure to account for worse QOL might undervalue interventions that prevent disability or terminal illness.

What makes cost-effectiveness and cost–utility analyses powerful is that diverse interventions may be compared and selected for their ability to provide maximum health benefit for money spent. For example, if healthcare dollars are limited, these methods allow some rational basis for recommending whether society should routinely provide coverage for a patient with acute myeloid leukemia (AML) in third complete remission scheduled for an unrelated donor HCT, or instead cover patients with congestive heart failure and severe diabetes who need heart transplants. Similarly, one can compare the healthcare gain of one high-cost treatment procedure, such as an autologous HCT for relapsed NHL, with the preventive strategy of providing statin therapy to several middle-aged men. Based on the cost/effectiveness ratio for hemodialysis, a procedure covered separately by the Federally funded Medicare program and thus available to all people, an acceptable cost/effectiveness ratio of <$50,000 per QALY has been proposed. A ratio of >$100,000 is questionable because that money applied elsewhere may buy better health for the population. A ratio between $50,000 and $100,000 per QALY is in the gray zone. Some countries, such as Australia and Canada, require information on cost-effectiveness prior to drug approval. Table 28.1 shows examples of published cost-effectiveness and cost–utility studies in HCT and some comparisons in other fields [20–28]. Online resources such as https://research.tufts-nemc.org/cear4/ contain comprehensive lists of cost analyses and patient utilities [29]. League tables help to put cost/effectiveness ratios into perspective.

Table 28.1 Examples of cost-effectiveness and cost–utility studies in hematopoietic cell transplantation (HCT) and medicine

Ref.	Year of publication	Treatment	Alternative	Cost/effectiveness ratio[a]
[20]	1989	Allogeneic BMT for AML	Conventional chemotherapy	$10,000/LY
[21]	1992	Autologous BMT for HD in 2nd CR	Conventional chemotherapy	$26,000/LY
[22]	1997	Autologous BMT for relapsed NHL	Conventional chemotherapy	$9200/LY
[28]	1998	Unrelated donor BMT for stable phase CML	IFN-α	$51,800/QALY
[23]	1999	Second allogeneic transplantation after relapse of acute leukemia	Conventional chemotherapy	$52,000/LY
[24]	2001	Autologous PBSCT for MM	Conventional chemotherapy	$23,300/LY*
[25]	1989	Smoking cessation program	No intervention	$1300/LY
[26]	1987	Hemodialysis	No dialysis	$50,000/LY
[27]	1990	Captopril for hypertension	No therapy	$72,000/LY

AML, acute myeloid leukemia; BMT, bone marrow transplantation; CML, chronic myelogenous leukemia; CR, complete remission; HD, Hodgkin disease; IFN, interferon; LY, life-year; MM, multiple myeloma; NHL, non-Hodgkin lymphoma; PBSCT, peripheral blood stem-cell transplantation; QALY, quality-adjusted life-year.

[a] £0.64 = $1.00.

It would be naïve to believe that costs do not affect access to HCT, although sometimes policies can be surprising. Gratwohl et al. found that countries with low or medium gross national incomes are performing the same number of HCTs for chronic myelogenous leukemia (CML), whereas the transplantation rate has fallen substantially in high-income countries. It is less costly overall for poorer countries to perform an up-front HCT than to pay for lifetime drug therapy or several years of drug therapy followed by eventual HCT [30].

What is the patient's experience with HCT?

Beyond the traditional biological end-points of survival and relapse reported in HCT studies, outcomes research tries to measure and put into perspective other factors that determine whether an intervention is ultimately judged a success or failure. Many of these factors are subjective (not directly observable) and are referred to as "constructs." For example, measurement of health-related quality of life (HRQOL, the QOL related to health, disease, and medical treatment) and patient utilities are considered part of outcomes research. Measuring these end-points relies heavily on methods developed for survey research, the collection of data directly from patients.

Qualitative methods

The goal of qualitative studies is to capture the breadth of possible patient attitudes or experiences. One forum is a focus group, in which 8–10 people are led by a moderator and discuss particular topics. Focus groups usually last about 2 hours, and participants may be paid a nominal amount for participation. They are often audio- or videotaped, with an additional researcher taking notes. The interactive nature of the communication process allows topics to be probed and ideas developed under the influence of group dynamics, which may lead to unexpected insights about the topic under discussion. Focus groups are often used for formative research to explore patient attitudes and opinions prior to launching a formal study.

Qualitative information may also be collected through interviews or open-ended survey questions. In contrast to the majority of studies in which generalizability is critical, the goal in truly qualitative studies is not to obtain a representative sample. In fact, "purposive" or targeted sampling can be performed to ensure representation of the spectrum of possible patient experiences. For example, if 80% of the population have a typical experience, 5% have a less typical experience, and the remaining 15% all have unique experiences, the goal would be to interview 17 people, one from the majority, one from the minority, and all 15 who had unique experiences. Usually, transcriptions are made of the interviews, and qualitative coding software is used to mark the transcripts for easier analysis. Transcripts are reviewed by a limited number of individuals who code them for themes, aggregate the concepts into broader groups if possible, and report on the range of patient experiences.

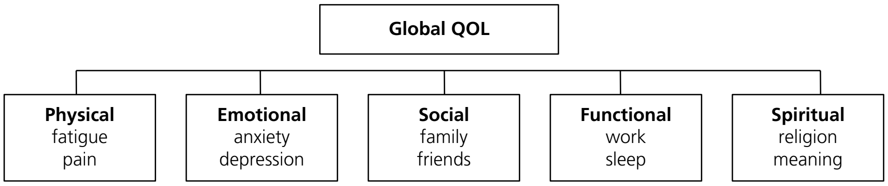
Qualitative methods have been used in several studies to evaluate aspects of recovery following HCT [31–34]. These studies revealed several themes that are not particularly well covered in standardized instruments, for example, strategies that patients use to compensate for limitations, multiple losses in all aspects of their lives and the greater appreciation for life brought about by the HCT experience.

Quality of life

Quality of life (QOL) is composed of diverse determinants, including physical abilities, symptoms, social well-being, psychoemotional status, and spiritual/existential experiences (for details regarding QOL after HCT see Chapter 33). QOL studies in HCT have generally sought to: (i) describe the long-term QOL, adaptation, and recuperation of patients, (ii) find predictors of better or worse QOL, and (iii) compare populations treated with different procedures. There are numerous, multi-dimensional, validated instruments available for measuring QOL in HCT. When scored according to psychometrically tested methods, they provide standardized QOL information that may be compared with other populations. One commonly used instrument is the Medical Outcomes Study Short Form 36 (SF-36), a generic multidimensional 36-item instrument that has been used on thousands of patients and healthy people to measure physical and mental health status [35]. Other cancer-specific instruments include the European Organization for Research and Treatment of Cancer (EORTC) Quality of Life Questionnaire (QLQ) C30 (30 items) [36–38] and the Functional Assessment of Chronic Illness Therapies (FACT) (27 items) [39]. Both cancer-specific instruments also offer HCT-specific modules that can be added to the core form to capture issues specific to HCT. There is a fee to use the SF-36 whereas the EORTC and FACT instruments are free for academic studies if the trial is registered. The instruments are available in multiple languages, and respondents must also be able to complete the survey in a language with which they are comfortable. It is a common mistake to assume that interpreters can administer English instruments to a non-English speaker. Instead, the validated version in the subject's native language should be used since interpreters may unintentionally change the meanings of items and responses. Figure 28.2 shows an example of the physical functioning scales from the core instruments. Of note, comparative studies have shown that despite similarly named subscales, instruments are actually measuring different constructs and it is difficult to compare studies unless they use identical instruments [40].

Since 2004, the Patient Reported Outcomes Measurement Information System (PROMIS) team has been working to create item banks for common domains of health and well-being (www.nihpromis.org). These items have not been used in HCT research yet.

Biostatistical methods for analyzing QOL data can be complicated because they must address issues of longitudinal data analysis, informatively missing data and other problems exacerbated by the nature of self-reported QOL data [41–44]. Repeated measures analysis and mixed models allow differences between populations and over time to be studied. Developing methods to place QOL differences into their clinical context is an active area of research. Although validated scales are psychometrically sound and allow comparison of treatment groups by statistical testing, the results of QOL studies are not intuitive to patients and physicians [45,46]. For example, a survival difference of 10% is easily interpretable, but many find it harder to interpret a QOL difference of 50 versus 35 on a given scale and place such an observation in its clinical context. There is no intuitive feeling for what a person with a score of 50 feels like compared with someone with a score of 35. To address this limitation, the concept of a "clinically meaningful difference" was introduced, defined as the difference in QOL that would prompt adoption of the intervention or a change in practice. It is the difference in a scale that is "noticeable" or "meaningful" to patients. There are two approaches to its determination: anchor-based and distribution-based. Anchor-based methods rely on patient-reported differences to determine what is clinically meaningful. For example, patients are asked a global change question such as, "Overall, is your QOL a lot better, a little better, somewhat better, somewhat worse, a little worse or a lot worse." This overall category is then compared with their QOL scores [47–49]. However, this method uses patient-perceived differences in QOL as the gold standard, raising the question of why we cannot just ask patients directly about changes in their QOL. The second approach is based on the statistical distribution of QOL



SF-36 (physical)
Does your health now limit you in…

- Vigorous activities, such as running, lifting heavy objects, participating in strenuous sports
- Moderate activities, such as moving a table, pushing a vacuum cleaner, bowling or playing golf
- Lifting or carrying groceries
- Climbing several flights of stairs
- Climbing one flight of stairs
- Bending, kneeling, or stooping
- Walking more than a mile
- Walking several blocks
- Walking one block
- Bathing or dressing yourself

EORTC (physical)

- Do you have any trouble doing strenuous activities, like carrying a heavy shopping bag or a suitcase?
- Do you have any trouble taking a long walk?
- Do you have any trouble taking a short walk outside of the house?
- Do you have to stay in bed or in a chair for most of the day?
- Do you need help with eating, dressing, washing yourself or using the toilet?

FACT (physical)

- I have a lack of energy
- I have nausea
- Because of my physical condition, I have trouble meeting the needs of my family
- I have pain
- I am bothered by side effects of treatment
- I feel ill
- I am forced to spend time in bed

Figure 28.2 Dimensions of quality of life and examples of the physical domain from validated questionnaires.

scores. Generally, a difference of half a standard deviation is considered to be clinically meaningful.

After HCT, patients generally rate their global QOL fairly highly despite many specific physical and emotional difficulties. One possible explanation for this paradox is called "response shift," the theory that perceptions of current QOL are more dependent on one's perspective than on one's actual health, and that this perspective changes with illness [50]. For example, consider two previously healthy patients with identical diseases, physical ailments, and social support systems. Upon diagnosis, the first patient believes he is afflicted with a terrible disease and embraces HCT as a life-saving procedure. Afterwards he compares himself with others who died, and rates his overall QOL fairly highly as a result of his response shift. The second patient considered himself healthy before the transplant despite his disease and reluctantly undergoes transplantation. After HCT, he pines for his previously healthy self and is very dissatisfied with his QOL. This patient did not have a response shift.

Results and conclusions of specific QOL studies are discussed in more depth in Chapter 33.

How are patient-reported measures developed?

Instrument (or survey) development is considered a facet of outcomes research because it establishes the validity of clinical tools to measure subjective end-points. In order for an instrument to be useful, it needs to reflect what it purports to measure (validity), be an accurate measure (reliability), separate people into clinically meaningful groups (discrimination), and detect important changes (sensitivity). Instrument development from scratch is a demanding process. First, a list of relevant concepts should be created from prior literature, focus groups, or other means of formative research. Then, a draft scale is created. Attention should be given to the wording of specific questions and response items to allow sufficient variability to capture the range of clinical conditions. A pilot study is then conducted with cognitive interviewing to ensure that patients understand the questions and are selecting response options consistent with their intent. Finally, a larger study is performed to document validity, reliability, and sensitivity. Many survey developers neglect the final step of confirming sensitivity to change. This is an important feature since many instruments are intended to describe the experiences of population subgroups, compare one population with another, or show changes over time.

Reliability refers to whether a measure is consistently reflecting the true status of a subject. Internal reliability is usually reported as a Cronbach's alpha (α) with acceptable values >0.7. Cronbach's alpha measures whether items are correlated with each other and measure the same underlying construct. Stability of measurements is reported as "test–retest reliability," the correlation between two measurements separated in time when an individual's status has not changed. The range is from 0 to 1.0, with higher values reflecting greater stability and values >0.5 generally considered acceptable. If test–retest reliability is <0.5 and the subject's clinical situation has not changed, the scale is probably susceptible to influences unrelated to the clinical status of the person.

Validity refers to whether an instrument is truly reflecting what it is supposed to measure, and is usually expressed as correlation coefficients or effect sizes. Content validity refers to how well the scale measures the different aspects of the construct. Convergent validity is demonstrated when the scale correlates highly with other scales measuring similar constructs, whereas discriminant validity means that there is little correlation with scales measuring unrelated concepts. Discrimination refers to the ability of the scale to separate people into clinically meaningful groups, whereas sensitivity to change means that as a person's clinical situation changes, they should score differently on the instrument. For example, Lee et al. developed a chronic GVHD symptom scale [51]. This scale was designed to be self-administered and brief (5 minutes) and to follow patients with chronic GVHD over time to detect improvement or worsening in their symptoms.

How can one combine information from several different data sources?

Registry studies

Several large transplant registries were established to provide national and international information on the outcomes of HCT. These include the Center for International Blood and Marrow Transplant Research (CIBMTR) (http://www.cibmtr.org), the National Marrow Donor Program (NMDP) (http://bethematch.org), European Group for Blood and Marrow Transplantation (EBMT) (http://www.ebmt.org), and Eurocord (http://eurocord.org). These registries collect, computerize, and make available data for analyses. Although they suffer from limitations common to registries, including incomplete capture of all procedures, problems with data standardization, validation issues, and difficulty obtaining detailed clinical information including long-term follow up, they also provide the only means for determining the effectiveness of HCT as practiced outside clinical trials and single institutions. Many important research questions can only be answered by registry studies because large patient numbers are required. Rarer diseases and clinical situations for which no single institution has adequate experience are also best approached by registry studies.

Large administrative databases have not been useful for HCT research in the past, with two exceptions. The Nationwide In-patient Sample provides a representative sample of inpatient hospitalization lengths of stay, costs, and hospital codes for more than 33 US states. This database has been used for some economic studies [52]. Majhail et al. used a private payer database to document the cost of autologous and allogeneic transplantation [7]. In 2006, the C. W. Bill Young Cell Transplantation Program mandated development of a Stem Cell Therapeutics Outcomes Database (SCTOD) in the United States to collect outcomes data on all procedures using allogeneic hematopoietic cells. This important resource is already providing a rich research database of population-based data on HCT use.

Decision analysis

There is rarely a definitive clinical trial or report that provides all the data necessary to settle a clinical question. Many people believe that they can weigh complicated decisions fairly, but research shows that this ad hoc approach is subject to serious cognitive biases and frequently results in suboptimal decisions. Decision analysis uses computer modeling to recommend the optimal treatment choice based on what is known about the probabilities and consequences of different treatment options [53]. Advanced programming capabilities allow the probabilities of different outcomes to vary depending upon a patient's characteristics, time from diagnosis, or prior clinical course, assuming such data are available.

The results of decision analysis provide a population-based approach to recommend an optimal treatment choice [54]. Comparisons of LYs or QALYs obtained from a decision analysis are not amenable to statistical testing in the classic sense, since p-values and confidence intervals (CIs) reflect the uncertainty in measurements and the likelihood of chance findings. In decision analysis, it is up to the reader to compare the gains in LYs or QALYs and determine if one treatment is optimal. Obviously, such comparison is easier when the survival benefit associated with one option is several years and the other offers several weeks. Published league tables can help put gains in life expectancy into perspective [55]. In practical terms, a decision analysis may not distinguish between one individual surviving an extra 10 years and five individuals surviving an extra 2 years, although patients may view these outcomes differently. Sometimes decision analysis can identify key pieces of information that *should* influence treatment decisions and, conversely, point out which considerations *should not* affect a rational decision. Several assumptions may be tested at the same time to see if any combination of values would change conclusions.

Many decision analyses have been performed in HCT. For example, an analysis of allogeneic bone marrow transplantation (BMT) versus periodic blood transfusion for patients with sickle cell anemia and elevated cerebral blood velocities suggested that either treatment approach was reasonable [56]. An analysis of immediate versus delayed HCT in patients with myelodysplastic syndrome (MDS) suggested that patients with intermediate-2 or high-risk MDS should undergo up-front HCT. In contrast, the population with lower risk MDS maximized their LYs with delayed HCT [57]. An analysis of allogeneic HCT versus chemotherapy for patients with AML in first remission suggested that HCT was beneficial for older patients with a related donor and younger patients with unfavorable cytogenetics [58].

Meta-analysis

Meta-analysis allows the results of several clinical studies to be aggregated, increasing the power of the analysis and enhancing confidence in the results [59–62]. This statistical technique is particularly useful in detecting treatment differences if negative studies are due to small sample size and lack of power. *Study-level* meta-analyses use individual studies as the unit of analysis. Results are displayed as point estimates and CIs for each study with some indicator (size of a dot, width of a box) to reflect relative study size. A diamond is often used to depict the aggregate estimate. Both randomized controlled trials and observational studies are often included in meta-analyses. *Patient-level* meta-analyses retrieve and analyze data on individual patients, although the source of each patient is incorporated into the analysis. For example, the Stem Cell Trialists' Collaborative Group aggregated patient-level data from nine randomized trials in human leukocyte antigen (HLA)-identical sibling HCT. The study concluded that peripheral blood is associated with decreased relapse rates and better overall and disease-free survival in patients with late-stage disease, but with the disadvantage of more extensive chronic GVHD [63].

All meta-analyses depend upon data available in the literature or otherwise attainable. Hence publication bias may significantly affect results. A funnel plot is a graphic that can help determine if a meta-analysis is likely to suffer from publication bias. Effect size is plotted against study size. If all studies are published and available regardless of their conclusions, then the plot should result in a funnel shape with the apex centered on the true value. This pattern occurs because the ranges of effect sizes are wider for the smaller studies due to statistical factors, whereas larger studies should provide results closer to the actual truth.

Evidence-based medicine

Critical reviews of the literature summarize the available evidence for or against certain practices, and they are often translated into practice guidelines. The methodology for evidence-based reviews is very well established and rigorous, although the specific terminology used to reflect the levels of evidence and grades of recommendation have evolved. A typical grading system for critical reviews is shown in Table 28.2, and is based on the type, frequency, and consistency of evidence [64].

Table 28.2 Levels of evidence and grades of recommendation

Level	Types of evidence
1++	High-quality meta-analyses, systematic reviews of RCTs, or RCTs with a very low risk of bias
1+	Well-conducted meta-analyses, systematic reviews of RCTs, or RCTs with a low risk of bias
1–	Meta-analyses, systematic reviews of RCTs, or RCTs with a high risk of bias
2++	High-quality systematic reviews of case–control or cohort studies; high-quality case–control or cohort studies with a very low risk of confounding, bias, or chance and a high probability that the relationship is causal
2+	Well-conducted case–control or cohort studies with a low risk of confounding, bias, or chance and a moderate probability that the relationship is causal
2–	Case–control or cohort studies with a high risk of confounding, bias, or chance and a significant risk that the relationship is not causal
3	Non-analytic studies, for example, case reports or case series
4	Expert opinion
Grade	**Grade of recommendation**
A	At least 1 meta-analysis, systematic review, or RCT rated as 1++, directly applicable to the target population or a systematic review of RCTs or a body of evidence consisting principally of studies rated as 1+, directly applicable to the target population and demonstrating overall consistency of results
B	A body of evidence including studies rated as 2++, directly applicable to the target population, and demonstrating overall consistency of results or extrapolated evidence from studies rated as 1++ or 1+
C	A body of evidence including studies rated as 2+, directly applicable to the target population, and demonstrating overall consistency of results or extrapolated evidence from studies rated as 2++
D	Evidence level 3 or 4 or extrapolated evidence from studies rated as 2+

RCT, randomized controlled trial.

One practical limitation of evidence-based reviews compared with consensus statements or clinical reviews is that the published evidence is strictly interpreted. Lack of randomized controlled trials in some areas can result in the frustrating conclusion that "evidence is insufficient to recommend for or against" a particular practice, even when widespread use seems to support its effectiveness [65]. However, the results of the Women's Health Initiative, showing that routine hormone replacement after menopause can cause more harm than good [66], and lack of efficacy seen in trials of autologous HCT for high-risk or advanced breast cancer [67–69], reinforce the idea that randomized trials provide the highest level of evidence for a practice.

Many organizations have produced evidence-based or consensus practice guidelines. A non-exhaustive list relevant to transplantation includes the American Society for Blood and Marrow Transplantation (www.asbmt.org), Cochrane Collaboration, Cancer Care of Ontario, National Comprehensive Cancer Network (NCCN) (http://www.nccn.org), and Physician Data Query (PDQ) (http://www.cancer.gov/cancertopics/pdq). However, relatively little research has evaluated the influence of practice guidelines on clinical practice and patient outcomes, and what has been published suggests less improvement than hoped for [70].

How can the practice of HCT be improved through health services research?

Access

Studies seeking to understand the non-medical barriers to appropriate healthcare are termed "access" studies. They generally focus on socioeconomic, political, cultural, and other non-biological factors. For example, internationally there is a strong association between transplant rate and team density, gross national product per capita, and healthcare expenditures per capita suggesting better access in some countries [71]. In the United States, ethnic and racial minorities have long been under-represented in HCT statistics for unclear reasons, and survival varies by racial group even after controlling for disease and transplant characteristics [72]. Neither GVHD nor relapse appears to explain the higher mortality seen in certain racial groups [73].

Unfortunately, one of the best data sources for access studies is not relevant for HCT. The linked SEER–Medicare database provides cancer-specific information and inpatient and outpatient billing data on approximately 14% of the US population, but is limited to patients aged 65 years or older [74]. The size and comprehensiveness of this database along with the fact that it is population-based have made it a tremendous resource for studies elsewhere in medicine. For example, researchers have found that African Americans are less likely than white Americans to receive screening examinations for cancer, to be diagnosed with cancer in its early stages, and to receive adjuvant therapy and aggressive care [75–81]. African Americans are also less likely to undergo some invasive procedures than white Americans, such as renal transplantation, even after correcting for clinical characteristics [82] and patient preferences [83]. However, once access to treatment is controlled, survival and DFS are similar between African American and white American patients, suggesting that the biological responses to treatment are comparable [84,85].

Quality of care

HCT has been relatively spared from scrutiny about quality of care. Significant practice variation has been tolerated and, in fact, encouraged, as a means of testing different approaches that could eventually improve the field of transplantation. The relatively low volume of procedures per center and the inevitable case mix differences have made it difficult to provide reliable standardized center statistics. Nevertheless, as part of its Health Resources and Services Administration (HRSA) contract, the NMDP has been reporting center-specific disease activity and risk-adjusted survival information for patients undergoing unrelated donor transplantation. Starting in 2008, the CIBMTR began collecting data on all allogeneic procedures performed in the United States as mandated by the SCTOD. They are also required to publish individual center outcome statistics, adjusted for the case-mix severity of the center's population (http://bloodcell.transplant.hrsa.gov/RESEARCH/index.html).

There is every reason to believe that greater attention to institutional and programmatic factors contributing to patient outcome may identify ways to improve care and decrease costs [86]. Volume–outcome and experience–outcome relationships have been documented in solid organ transplantation and complicated surgical procedures [86–89]. A time-series study of costs during autologous HCT for NHL suggested that technological advances and learning curve effects (institutional familiarity with a procedure tends to improve outcomes) probably both contribute to falling costs, although the study was not designed to compare clinical outcomes [90]. Loberiza et al. found that lower 100-day mortality for allogeneic recipients was associated with a higher patient-per-physician ratio and centers where physicians answer calls after hours [91].

From a regulatory perspective, accreditation by the Foundation for the Accreditation of Cellular Therapy (FACT) ensures compliance with standards for clinical care and cell processing facilities. Programs are required to show evidence of documentation, standard operating procedures, and quality management programs. Increasing Federal oversight of outcomes reporting through the SCTOD will provide both a tool for quality monitoring and improvement and also a wealth of research data that can address health services questions [92]. In Europe, accreditation by the Joint Accreditation Committee of ISCT-Europe and EBMT (JACIE) has been associated with better outcomes [93].

Practice variation

The term "practice variation" refers to systematic heterogeneity in clinical practice unjustified by medical considerations. Undesirable practice variation results from external influences on physicians (e.g. training, practice environment, reimbursement structure) [94], patient characteristics (e.g. race, ethnicity, gender, and age, if these features should not influence treatment choice), and lack of definitive evidence for the effectiveness of various procedures [5]. In some contexts, practice variation is considered a measurement of poor quality care. Within HCT, wide practice variation has been noted in infectious prophylaxis and compliance with published guidelines [95], supportive care [96], and medical decision-making [97]. By studying outcomes associated with current heterogeneous approaches, it is hoped that we can narrow variation towards more effective practices.

Conclusion

Outcomes and health services research seeks to answer questions that are relevant as a procedure matures beyond the experimental phase – What are the costs of providing these services? Is society getting its money's worth? What do patients experience with the procedure? How do you pull together disparate sources of data (now that they are available)? Is the procedure equally available to all people and of the highest possible quality? Answers to these questions are moving targets as HCT evolves. Nevertheless, for people afflicted with diseases treated by HCT and societies trying to control healthcare spending, decisions have to be made today. Outcomes research tries to provide the necessary data so that personal and societal decisions can be based on the best information available.

CHAPTER 29

The Evaluation and Counseling of Candidates for Hematopoietic Cell Transplantation

Bart L. Scott and Brenda M. Sandmaier
Fred Hutchinson Cancer Research Center and University of Washington, Seattle, WA, USA

Introduction

One must begin by acknowledging that there is a lack of clinical trial data regarding the appropriate work-up and counseling of transplant patients. Much of the dogma that is currently in place is based on experience and opinion rather than clinical trial results. Patients who are under consideration for hematopoietic cell transplantation (HCT) require a careful clinical evaluation and in-depth counseling by experienced physicians, nurses, and a knowledgeable social worker at the respective transplant center. Most transplant candidates are referred by practicing hematologists or oncologists to the tertiary center where the transplant procedure will be performed. Information regarding the prior course, including initial diagnostic studies, previous drug and radiation treatments, and responses to these interventions, and also psychosocial aspects of the transplant candidate, are of the utmost importance.

Written information for patients

Prior to the time of the initial meeting with the medical and paramedical staff at the transplant center, patients should have received at least some written educational material regarding the rationale, principle, potential complications, and projected treatment results of HCT. An increasing number of patients are obtaining information from the Internet and may be fairly knowledgeable and informed (or misinformed) based on the quality of the material that they are able to acquire.

Many transplant centers have developed their own center-specific written information, together with educational videotapes or compact discs, which are mailed to future patients and their families in advance of their first clinic visit. Another excellent source of general information is the Blood and Marrow Transplant Information Network. The Network maintains a website (www.bmtinfonet.org) (for further details, see Chapter 35).

It may be extremely helpful for transplant candidates to communicate with former transplant recipients who can share their experience with the future patient. Such contacts are much more valuable than the visit to so-called Internet "chat rooms" that the present authors consider to be "goldmines for misinformation."

The patient's first visit to the transplant center

For many patients, their first visit to the transplant center is an initial consult to determine if transplant is indicated. This is followed by an explanation of the potential risks and benefits of HCT for an individual patient. The physician should form an impression as to whether the examination and the medical data identify the patient as a suitable transplant candidate. Conversely, the patient should be provided with well-organized general and also individualized information about the intended treatment course, potential complications, expected transplant outcome, and alternative procedures. With most patients, the communication should occur in lay language. Technical terms should be explained and abbreviations be avoided whenever possible. Simple illustrations can be particularly valuable, and a glossary may prove to be very helpful. Conversely, some patients are already very well informed, and time at the counseling meeting may be spent more effectively on discussion of specific issues.

Until they become ill, most patients have never heard words such as "allogeneic," "autologous," "haplotype," "graft-versus-host disease" (GVHD), and so on. The concept that a small number of donor stem cells can restore the entire bone marrow with all its production of blood cells needs to be explained. A well-informed patient is much more likely to participate actively in his or her future care.

Finally, we need to be most careful with the terminology that we introduce to our patients. A word such as "mini-transplant" implies to most listeners that this must be a minor procedure and nothing can go wrong. Consider that, even at the most experienced centers, the day 100 non-relapse mortality (NRM) after a reduced-intensity allogeneic HCT is at least 5%, and at 2 years it reaches approximately 20%. What will be your response to the spouse, parent, or child of a dying patient when the question is asked how a "mini"-procedure could directly or indirectly lead to a patient's demise?

Advice on counseling new patients

Each physician and clinical investigator should develop his or her own approach to the education of patients and the counseling process. As Dr. Karl Blume has previously written, a simple four-question

Thomas' Hematopoietic Cell Transplantation, Fifth Edition. Edited by
Stephen J. Forman, Robert S. Negrin, Joseph H. Antin and Frederick R. Appelbaum.

answer system is very useful in the initial counseling of patients (why, how, when, and what?):

1. *Why* is HCT being done?, i.e. the rationale for the procedure and discussion of alternative therapies.
2. *How* is the procedure performed?, including the explanation of side effects from the preparatory regimen, the transplant process itself (including the impact on an allogeneic donor), the description of the reason for and clinical presentation of GVHD, the efforts for the prevention of GVHD, and the potential risks for other early or late side effects and relapse.
3. *When* should the procedure be performed?, for example, very soon in the case of relapsed acute leukemia, or electively for patients with multiple myeloma who may have several months or sometimes years until the preparation for HCT is begun.
4. *What* is the projected treatment outcome for the individual patient who is being evaluated? It is advisable to quote a range of percentages for disease-free survival (DFS) and not a precise figure, which would be arbitrary at best.

Patients may elect to tape the conversations in order to review the information presented to them at their leisure. The physician should also encourage the patient to take notes and to write down questions that may come up between meetings or at a later time. It is also our practice to send a copy of the initial consult letter to the patient, which can be reviewed at a follow-up meeting. An atmosphere of trust between patients and their families and the transplant team is of the greatest importance for the long weeks before, during, and after the transplant procedure. The more carefully patients are prepared for the difficult phases of HCT and the more they understand the rationale for diagnostic and therapeutic procedures, the significance of expected (and sometimes unexpected) events, and the risks of the entire medical approach, the easier will be the task of the healthcare team to guide these often frightened individuals through one of the physically and emotionally most challenging times of their lives. Issues such as the potential use of life support need to be addressed before the preparation for HCT is begun. Some 10% of HCT recipients require admission to an intensive care unit, most often during the first 2 months after HCT, and only a few of such unfortunate patients recover [1,2]. Despite improvements in the care of critically ill patients, recent reports continue to indicate a mortality rate of 87% in patients who require mechanical ventilation following HCT [3].

It may take years for physicians to gain the necessary experience, medical knowledge, and sound clinical judgment to counsel their patients "perfectly." Personally, we have found this to be an area of continuous process improvement, and it has become clearer over time that consultations are not only tailored to specific diseases, but also to expectations and baseline knowledge of individual patients. It obviously requires a high level of comfort to present a medical procedure that is offered with curative intent but is also associated with significant procedure-related morbidity and mortality. Even under optimal conditions, autologous HCT is associated with an approximately 5% early fatality rate, and still 10–25% of recipients of allogeneic HCT succumb sooner or later to non-relapse causes of death, including GVHD or GVHD-associated complications such as overwhelming infections, sinusoidal obstruction syndrome, prolonged immunodeficiency, or secondary malignancies.

The patient and the family members need to hear from the counseling physician that the intended treatment planned to provide a cure of the life-threatening disease may – in the case of one of the potentially severe complications – lead to the patient's early demise. Still, much of what is explained during the pre-transplant meetings is frequently forgotten when devastating complications occur later on. The special situations of desperate patients and their families explain why often little information from the counseling meeting is retained. Therefore, patients should be provided with written copies of the initial consultation if possible. A randomized trial performed in cancer patients demonstrated that an audio tape enhanced patient satisfaction and improved recall of diagnostic information [4].

End-of-life issues need to be addressed early. Many patients may hesitate to bring this issue up but are actually relieved to talk about it openly when encouraged. This complex problem is particularly important in families with complex relationships (in couples who are separated but are not divorced and in couples who are not married; sometimes, there are children, siblings, parents, or step-parents who want to make decisions later on but are not entitled to do so by the patient). Therefore, it is important to address these issues at the beginning of a patient's course rather than at the end, when frequently they may be so incapacitated that they are unable to participate. Retrospective analyses have shown that overall survival is better in those for whom advanced care planning discussions have taken place [5].

Table 29.1 lists issues and topics that should be addressed during the counseling meetings with transplant candidates. This list is only a guideline and should be reduced or expanded as appropriate by each transplant physician and for each patient under evaluation.

The problem of permanent infertility

For many young transplant candidates, the high probability of permanent infertility after high-dose therapy and HCT represents a major problem. Modern technologies such as cryopreservation of sperm and fertilized eggs can be used to overcome this serious issue in only a limited number of patients. Unfortunately, the ejaculates of many younger men are aspermic or hypospermic due to the effects of prior combination chemotherapy used for remission induction treatment. In the case of many younger women, the procedures to harvest eggs for in vitro fertilization fail. Despite successful fertilization, the number of those in whom a viable post-transplant pregnancy occurs is still extremely low.

A small number of patients, men and women, have spontaneously recovered reproductive function, with healthy children being born during the years after HCT [6]. These patients were usually children or adolescents at the time of HCT. It cannot be predicted at the time of HCT which patient will be able to regain fertility. However, it should be noted that patients conditioned with high-dose cyclophosphamide as therapy for aplastic anemia often are able to have children during the years following HCT. For more on the psychologic and physiologic aspects of infertility, sexuality, quality of life, and delayed long-term effects after HCT, the reader is referred to Chapters 32, 33, 34, and 104.

The recent introduction of reduced-intensity regimens into the field of HCT may result in a higher number of patients from both genders who retain or recover fertility. Since such regimens have so far included mainly older individuals, the information regarding this important issue is still lacking; however, cautious optimism seems to be justified.

Table 29.1 Issues and topics that should be addressed during counseling meetings with transplant candidates and their families

- I. Rationale (why is HCT offered to you?)
- II. Principle (how is HCT performed?)
  - A. Autologous versus allogeneic HCT
  - B. Preparatory regimen
    - 1. Choice of a high-dose or reduced-intensity regimen (with or without irradiation)
    - 2. Risks associated with high-dose therapy
      - a. Nausea, emesis, diarrhea
      - b. Fluid retention
      - c. Venocclusive disease/sinusoidal obstruction syndrome
      - d. Pancytopenia, immunosuppression, and associated infectious complications
      - e. Mucositis and pain in the oral cavity and throat
      - f. Hemorrhagic cystitis after cyclophosphamide
      - g. Cardiomyopathy after cyclophosphamide
      - h. Dermatitis after etoposide
      - i. Pneumonitis after nitrosoureas
      - j. Need for transfusion support
      - k. Temporary or permanent alopecia, especially after busulfan
      - l. Infertility
      - m. Cataracts
      - n. Second or secondary malignancies
  - C. Hematopoietic cell grafting
    - 1. Marrow versus peripheral blood cell graft
    - 2. Risks associated with infusion of a hematopoietic cell graft
      - a. Allergic reactions
      - b. Discomfort from cryoprotectant
      - c. Graft failure and graft rejection
  - D. Risks for GVHD
    - 1. Symptoms and prognosis of acute GVHD
    - 2. Need for drugs to prevent/treat acute GVHD
    - 3. Side effects of immunosuppressive drugs
    - 4. Symptoms and prognosis of chronic GVHD
    - 5. Drugs to prevent/treat chronic GVHD
    - 6. Immunodeficiency resulting from GVHD including bacterial, fungal, viral, and other infections
  - E. Risk of relapse after HCT
  - F. Risk of mortality after HCT
    - 1. Financial affairs, a will
    - 2. Durable power of attorney for health care
    - 3. Use of life support
- III. Timing of transplant (when should the procedure be performed?)
    - 1. Very soon, e.g. progressive acute leukemia
    - 2. Within weeks or few months, e.g. acute leukemia in remission
    - 3. Elective HCT, e.g. follicular small cleaved lymphoma in early stages
- IV. Projected result (what can the candidate expect from HCT?)
    - 1. Underlying disease and remission status
    - 2. Compatibility of donor–recipient pair
    - 3. Performance status of candidate
    - 4. Comorbid conditions
    - 5. Prior therapies
    - 6. Nutritional status
    - 7. Age of HCT candidate
    - 8. Previous infections
    - 9. Transfusion history
    - 10. Other individual aspects
- V. Other important issues
    - 1. Banking of sperm, in vitro fertilized eggs
    - 2. Habits such as nicotine, alcohol, or drug addiction
    - 3. Need for active participation by patient and caregiver during entire course
    - 4. Rationale and need for clinical trials including randomization
    - 5. Duration of stay in the area of the transplant center
    - 6. Return to home and work
    - 7. Sexual activities
    - 8. Time to full recovery
    - 9. Quality of life issues

The choice of transplant procedure

Most patients arriving at a transplant center have been told by their referring physician that they are in need of a transplant procedure. Many of them are surprised when they hear that there are many different types of HCT: autologous HCT, allogeneic HCT, and occasionally syngeneic HCT. The counseling physician has to use their best judgment and knowledge, together with the experience at the respective transplant center, to advise the patient concerning the type of procedure that has the greatest likelihood of success for the candidate's particular condition.

Which outcomes data should one quote?

The single most important issue for the patient is the expected overall survival. Information described below indicates that the remission status and patient age are the most predictive factors – with age losing some of its prognostic power with the current use of reduced-intensity regimens. Ideally, each transplant center would have a rich database from which one could generate information pertaining to each disease, remission status, age, and so on. In the absence of such a powerful tool, which data should be quoted by the counseling physician?

Recent studies involving 163 HCT centers in the United States indicate a significant "center effect," that is, 100-day mortality after allogeneic HCT was lower in centers with a higher patient-per-physician ratio and in those centers where physicians answered calls after office hours [7]. The data from a less experienced center are likely to be less favorable. The patient counseled at that center should either be quoted center-specific results (if available) or the relatively representative data from the large national and international bone marrow transplant registries.

What does the patient hear and remember?

The patient comes to the transplant center with the expectation of being cured. Much of the information provided during the counseling meetings is viewed and interpreted by the patient in a more favorable light than is actually realistic. An important analysis has previously been reported from the Dana Farber Cancer Institute indicating significant discrepancies between patient and physician estimates for the success of HCT [8]. In this prospective study, 313 autologous or allogeneic HCT recipients and their physicians responded to baseline and follow-up questionnaires concerning their expectations for cure with or without HCT and for treatment-related mortality. Information on actual treatment-related mortality and disease-free 1-year survival was subsequently available for 263 patients. The data are given in Table 29.2. Patients and their physicians had the most concordant and accurate expectations when the outcome of HCT was likely to be favorable. However, patients with more advanced diseases failed to recognize the higher risk associated with their situations. This important study illustrates the urgent need to improve further the communication with transplant candidates.

The second counseling meeting

After the first visit to the transplant center, the patient should be allowed adequate time (several days) to consider the often overwhelming nature and amount of information. In a second meeting, the transplant physicians should assure themselves that the patient understands the whole impact of the proposed treatment, both in general and in its details. An adequate amount of time should be set aside to address all issues and questions concerning the planned treatment and its potential complications.

During the second meeting with the patient, the issue of advanced care planning, including the need for arrangements of financial affairs, a will, Durable Power of Attorney of Health Care, and the

Table 29.2 Discrepancies between patient and physician estimates for the success of HCT [8]

		Estimate				
Type of Transplant	**No. of Patients**[a]	**Cure without stem cell transplantation (%)**		**Cure with stem cell transplantation (%)**		**Actual percentage with Disease-Free Survival (95% confidence interval)**[b]
		Patient	**Physician**	**Patient**	**Physician**	
Autologous[c]	94	20	7	70	32	44 (30–58)
Allogeneic	169					
Disease status						
Early	78	20	8	80	62	52 (40–64)
Intermediate	71	13	7	73	42	32 (21–44)
Advanced	20	19	7	80	31	10 (0–23)

[a] Five patients did not provide an estimate of cure without stem cell transplantation and 3 did not provide an estimate of cure with stem cell transplantation.

[b] At 2 years.

[c] Ninety patients with intermediate and 4 patients with advanced disease.

possible use of life support (if indicated), are to be tactfully but distinctly presented and discussed. A study on 155 HCT recipients indicated that 69% reported having designated a healthcare proxy, 61% had prepared an estate will, and 63% had discussed their wishes regarding life support with family and friends. In contrast, only 16% had communicated their choice of life support to their clinicians [9].

When to advise against HCT

No firm rules for a minimal success rate can be established that would be generally applicable. The patient and the entire healthcare team need to keep in mind that a long-term 10% DFS rate implies that nine of 10 patients sooner or later succumb to either relapse or NRM. For example, most patients with active central nervous system (CNS) leukemia have already received CNS therapy including irradiation prior to arrival at the transplant center. They will require further CNS treatment (irradiation and intrathecal drug instillations), which puts them at a high risk for leukoencephalopathy, a devastating, debilitating complication. Although not all such patients end up with extensive intellectual deficits, such long-term complications need to be considered carefully, especially because even less extensive neurologic manifestations can severely affect the future quality of life of the transplant recipient.

Patients with acute leukemia whose disease has recurred several times represent a similar dilemma. The chances that their underlying disease will persist or recur after HCT are exceedingly high. Unless innovative treatment concepts to overcome resistance are pursued in the form of exploratory research trials, these patients should be advised against HCT.

Of course, the patient is expecting that everything possible is going to be done, and many transplant physicians forget – while counseling such desperate patients – that the long-term transplant outcome data, for example for patients with acute leukemia in relapse, are extremely disappointing [10]. Finally, subjecting a volunteer unrelated donor to the physical and emotional stress of marrow donation for a patient with refractory disease and a very poor prognosis requires serious consideration. How often in our decision-making process before HCT do we think about the donor, and how often do we think about this volunteer once the graft is infused? Honestly, rarely. A negative outcome of a transplant effort affects many donors for months or even years. They may suffer feelings of loss, failure and – fairly often – guilt, especially if the patient dies of GVHD. Needless to say, the same issues apply to all related donors; for details concerning HCT donors, see Chapter 37.

How to counsel patients seeking multiple opinions

Receiving the diagnosis of cancer is one of the most devastating events in the life of any human being. It is certainly understandable that patients are very concerned about their future health and wish to obtain the best treatment that could restore their natural life expectancy. Therefore, many patients seek second or even more opinions, especially when it comes to risky procedures such as HCT. We all have met these "traveling" patients who arrive at the transplant center with stacks of computer printouts to obtain another opinion. They are clearly in need of very careful guidance. These consultations often take several hours.

We need to explain that the HCT procedures performed at most centers differ only in one or the other detail. In principle, we employ the same concepts, be it high-dose or reduced-intensity regimens, followed by infusion of hematopoietic cells. It is the experience and the care provided at a particular transplant center that make the difference. Moreover, many academic centers may offer innovative approaches that are tested in the setting of clinical research trials and are not available at other institutions.

It is the task of the counseling physician to guide the concerned and often confused patient to a most important decision while objectively explaining the pros and cons of one versus the other method, for example, T-cell depletion of the graft at the Memorial Sloan Kettering Cancer Center in New York versus post-transplant immunosuppression of the host at the Fred Hutchinson Cancer Research Center or the Stanford Hospital and Clinics. In this situation, the patient–physician relationship returns to its basic meaning. There is no room for dogma. Ultimately, most patients will decide in favor of the center at which they feel most comfortable and where they understand the rationale for one or the other approach.

The new foreign patient

Many patients from other countries are unfamiliar with the American insistence on discussing all pertinent issues openly with them and their families. They may be more accustomed to having unpleasant facts glossed over. Also, there may be many different dietary preferences and regulations, making it advisable to involve a dietitian early on. Rules on body invasion (endoscopy, biopsy, and autopsy) are important considerations requiring particular explanations and great sensitivity. No detailed rules can be provided in this chapter, as the expectations and needs vary with patients from different countries of origin. The issue of preferred language should be addressed prior to the arrival of any patient, and appropriate interpretative services are a vital component of patient education and informed consent. Family members should not be expected to serve as an interpreter for the patient as this could lead to intrapersonal conflicts relating to full disclosure of information. For example, some family members may decide that they do not want to burden their loved ones with negative information. Furthermore, it is difficult for family members to provide emotional support and serve as an interpreter at the same time.

The issue of clinical trials

All progress made during the past 50 years in the field of HCT is based on well-designed preclinical experiments and carefully conducted prospective clinical trials. Almost every transplant center is engaged in one or, more commonly, several clinical trials. Without patient participation, such important investigations are never possible. Therefore, all patients should be informed about clinical research trials as early as possible and be encouraged to consider enrollment in studies as part of their HCT procedure. The concept that a patient simultaneously serves as a research subject and the physician accepts also the role and responsibility of a clinical investigator should be explained during the first and subsequent counseling meetings. The rationale for clinical research studies should be addressed.

Most patients and some referring physicians do not have a clear understanding of the rationale of and need for randomized trials. These clinical research efforts are made to define how a new treatment compares with a previously utilized approach. It should be explained to the patient that the "new arm" might be better than, the same as, or worse than the "old arm." If the answer were known, the trial would be superfluous.

During either the first or second meeting, the patient should receive a copy of the written informed consent for his or her perusal. Non-English-speaking patients regularly need assistance from interpreters, and – depending on the region of the transplant center – informed consent documents are routinely provided in other languages. The consenting process itself should be completed only after all questions have been satisfactorily answered and should meet both institutional and Federal standards. Investigators with a conflict of interest need to provide pertinent information to their patients.

Conditions affecting treatment outcomes

A number of pre-transplant factors and conditions strongly influence the treatment outcome and thus impact the advice to patients regarding their candidacy for HCT.

Disease and remission status

This literature will provide the most up-to-date information on the treatment outcomes of autologous or allogeneic HCT for the many different diseases during the various remission stages. The extent of the underlying disease and its sensitivity to chemotherapy strongly influence the treatment result for recipients of autologous and allogeneic hematopoietic transplants. The reader will find multiple examples of the effect of the pre-transplant remission status on long-term DFS, for example, in acute leukemia, non-Hodgkin lymphoma, and most other conditions.

In order to evaluate a patient's candidacy for HCT, the most recent clinical information regarding the extent of the underlying disorder must be reviewed or must be obtained newly if the previous information is no longer considered to be accurate. For example, a patient with acute leukemia referred during first complete remission should undergo another bone marrow examination if the previous study was performed more than 1 month earlier. Appropriate diagnostic procedures (biopsies and cytogenetic and molecular methods) must be selected to assess the extent of current disease activity. For some conditions, for example, the myelodysplastic syndromes, recommendations concerning the timing of HCT have been proposed [11]. These decision analyses are based on a widely used International Prognostic Scoring System, which includes cytogenetic findings, number of blasts, and blood cell counts.

Patients with acute bone marrow injury following exposure to toxic agents may require a new assessment of their marrow cellularity and function to detect whether there are signs of spontaneous recovery obviating the need for the transplant procedure.

Candidates referred for autologous HCT who have received extensive and prolonged therapy with drugs (especially alkylating agents) and irradiation require detailed cytologic, cytogenetic and – if feasible – molecular analyses of their bone marrow to rule out any clonal abnormalities that would predispose them to later myelodysplastic or leukemic conditions [12,13].

Patients with solid tumors, regardless of their assumed stage, should be restaged to rule out new metastatic disease to the brain, liver, or elsewhere, conditions that are considered strong prognostic indicators for early relapse after HCT.

Compatibility of the donor–recipient pair

Many patients referred to a transplant center for allogeneic HCT have been previously tissue-typed, and an intended donor has been identified at that time. The transplant center should repeat the histocompatibility testing at its own laboratory to confirm the accuracy of the typing data. After all, the transplant team assumes responsibility for the future care of the transplant candidate; hence the expense of repeated laboratory procedures is fully justified.

Tissue-typing information influences the candidacy for allogeneic HCT and, therefore, the discussion with future patients during the counseling meeting. Granulocyte colony-stimulating factor mobilized peripheral blood stem cells (PBSCs) with unrelated donors have now become the most commonly used graft source for patients undergoing allogeneic HCT [14].

The field of HCT from unrelated donors has made remarkable strides during the past two decades, in particular, through the improved understanding of the major histocompatibility complex (see Chapter 10) and the introduction of molecular human leukocyte antigen (HLA) typing methods for donor selection [15–18]. The transplant center should assume the primary direction and the responsibility in the search for the unrelated donor. The success rate of HCT from unrelated donors is improving continuously and is comparable to results obtained with HLA-identical sibling donors based on large retrospective analyses [19–25]. Despite these improvements, the preferred source for allogeneic HCT remains an HLA-identical sibling over a younger HLA-matched unrelated donor [26].

A randomized trial comparing PBSCs with bone marrow from unrelated donors has been completed [27]. There were no significant differences in overall survival or relapse rates, but there was a higher incidence of chronic GVHD in patients who received peripheral blood stem cells from an unrelated matched donor. A similar trial performed with related donors showed an improved DFS in recipients who received PBSCs compared with bone marrow stem cells [28]. Long-term follow-up of the patients randomized to receive PBSCs indicated no significant differences between the two groups with regard to incidence of chronic GVHD or duration of immunosuppressive therapy, thus indicating that the optimal stem-cell source may be modified by whether the donor is unrelated or related. With regard to safety concerns of the donor, long-term results demonstrated the safety of PBSC mobilization in 3928 donors with no evidence of increased incidence of leukemia [29]. More details are provided in Chapter 41.

The utilization of alternative donor sources such as cord blood [30] and haploidentical donors [31] has increased in recent years. Thanks to these alternative donor sources, more patients now are able to undergo stem-cell HCT successfully. Several questions remain regarding the utility of these donor sources in various hematological malignancies. The best choice for an alternative donor source may depend on specific patient or disease parameters. A randomized trial comparing haploidentical donor stem cells with cord blood stem cells in patients with leukemia or lymphoma and no matched related or unrelated donor is currently accruing patients through the auspices of the Blood and Marrow Transplant Clinical Trials Network (BMT CTN).

Performance status

The invasive nature of high-dose cancer therapy, with or without irradiation, always causes some extent of regimen-related toxicity, sometimes resulting in little or, at other times, extensive morbidity and NRM. Therefore, the transplant candidate must be in good-to-excellent condition when preparation for HCT is begun. The performance score system introduced more than 60 years ago by Karnofsky et al. is still a useful tool for the clinician in the assessment of patients [32]. It has been generally accepted that a patient's performance score should be 70% or above to qualify for HCT. Most cooperative groups follow this requirement for patient enrollment, although some groups have introduced their own scoring system; for example, the Eastern Cooperative Oncology Group uses a 0–3 score, with 0 being asymptomatic and without any evidence of disease.

The Karnofsky scoring system was adapted for HCT recipients by Sullivan and Siadak [33] (Table 29.3). This grading system can also be used to describe the performance status following HCT. By definition, the best score early after HCT is 70% (on day 100 following allogeneic HCT).

The previous need to be a young, vigorous patient even to be considered for HCT has changed considerably over the past 10 years. Reduced-intensity conditioning regimens have been introduced and explored in rapidly growing clinical trials [34–41]. This novel approach relies heavily on the graft-versus-malignancy effect derived from donor T cells. Because of the less toxic side effects of the low-dose preparatory regimens compared with the previously used high-dose combinations, the extensive morbidity of the first few weeks following HCT is not encountered in this setting, and it is possible to perform these kinds of procedures on an outpatient basis. With reduced-intensity regimens, it is possible to treat older patients and others who would previously have been excluded because of serious comorbid conditions. Therefore, age alone is no longer considered as a contraindication for allogeneic HCT [42]. Increasing evidence points to a greater emphasis on underlying comorbidities or physiologic age rather than actual age [43]. This approach has been greeted with a great deal of enthusiasm, partially explaining the poorly chosen term "mini-transplant." However, we should realize that these HCT recipients still face all the serious clinical transplant-related problems of allografting for malignancy, namely GVHD, infections, and relapse. The only major aspect that has changed is the lack of toxicity previously observed during the first post-transplant month. Retrospective studies in a variety of hematologic malignancies have consistently shown no major differences in overall survival between high-dose and reduced-dose conditioning intensity [44–51]. However, the cause of death is different as patients who receive high-dose conditioning are more likely to die from toxicity of conditioning, whereas patients who receive reduced-intensity regimens are more likely to die due to relapse [52,53]. A prospective randomized trial comparing high-dose with reduced-dose conditioning intensity in patients with acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS) who are in morphologic remission is currently accruing patients and is operating under the auspices of the BMT CTN.

Table 29.3 Karnofsky performance status scale [32]

Index	Specific criteria	General
100	Normal, no complaints, no evidence of disease	Able to carry on normal activity; no special care needed
90	Able to carry on normal activity, minor signs or symptoms of disease	
80	Normal activity with effort, some signs or symptoms of disease	
70	Care for self, unable to carry on normal activity or to do work	Unable to work, able to live at home and care for most personal needs, varying amount of assistance needed
60	Requires occasional assistance from others but able to care for most needs	
50	Requires considerable assistance from others and frequent medical care	
40	Disabled, requires special care and assistance	Unable to care for self, requires institutional or hospital care or equivalent, disease may be rapidly progressing
30	Severely disabled, hospitalization indicated, but death not imminent	
20	Very sick, hospitalization necessary, active supportive treatment necessary	
10	Moribund	
0	Dead	

Prior and maintenance therapies for the underlying diseases

Every drug and every exposure to radiation administered since the time of the original diagnosis of the underlying malignancy have long-lasting cumulative effects on the patient. For example, the treatment with standard doses of radiation in the form of a mantle field for Hodgkin disease given a decade earlier may pose a significant risk factor if such a patient becomes a transplant candidate and is considered for total body irradiation (TBI) or for treatment with high doses of nitrosourea drugs. The cumulative effect of anthracyclines, which are widely employed in the standard therapy of leukemias and lymphomas, is well known and may limit the further tolerance of cardiotoxic drugs that are under consideration for use in preparatory regimens. Fortunately, newer agents may have less untoward effects, as was demonstrated for imatinib when administered to patients with chronic myelogenous leukemia (CML) prior to allogeneic HCT [54], and this drug even seems useful in the prevention of post-HCT relapse of patients with Philadelphia chromosome-positive acute lymphoblastic leukemia (ALL) or high-risk CML [55]. Also, rituximab, which is widely employed in the pre-HCT therapy of patients with all variants of

Table 29.4 HCT-specific comorbidity index score [87]

Comorbidities	Definition	Score[a]
Migraine/headache		0
Osteoporosis		0
Osteoarthritis		0
Hypertension		0
Gastrointestinal	Including inflammatory bowel disease	0
Mild pulmonary	DLCo and/or FEV_1 >80% or dyspnea on moderate activity	0
Mild renal	Serum creatinine 1.2–2 mg/dL	0
Endocrine		0
Bleeding		0
Coagulopathy	Deep venous thrombosis or pulmonary embolism	0
Asthma		0
Arrhythmia		1
Myocardial	Coronary artery disease, congestive heart failure, history of medically documented myocardial infarction, EF ≤50%	1
Mild hepatic	Chronic hepatitis, bilirubin >ULN – 1.5 × ULN, or AST/ALT > ULN – 2.5 × ULN	1
Cerebrovascular accident	History of transient ischemic attack or cerebrovascular accident	1
Morbid obesity		1
Diabetes	Requiring treatment	1
Depression/anxiety		1
Infection	Requiring continuation of treatment after day 0	1
Rheumatologic	Systemic lupus erythematosus, rheumatoid arthritis, polymyositis, mixed connective tissue diseases, polymyalgia rheumatica	2
Moderate pulmonary	DLCo and/or FEV_1 66–80% or dyspnea on slight activity	2
Peptic ulcer	Patients who have required treatment	2
Moderate–severe renal	Serum creatinine >2 mg/dL, on dialysis, or prior renal transplantation	2
Valvular heart disease	Except mitral valve prolapse	3
Prior solid tumor	Requiring treatment with chemotherapy	3
Moderate–severe hepatic	Liver cirrhosis, bilirubin >1.5 × ULN, or AST/ALT >2.5 ×ULN	3
Severe pulmonary	DLCo and/or FEV_1 ≤65% or dyspnea at rest or requiring oxygen	3

[a] Total score is the sum of all comorbidities present at time of HCT.

B-cell lymphoma, can be given as a consolidation measure after autologous HCT [55]. Finally, the concept of "total therapy" for multiple myeloma revolves around extensive combination therapy, which is continued at reduced intensity after autografting [56,57]. Randomized studies evaluating agents such as FLT-3 inhibitors in AML and oral hypomethylating agents in MDS are planned as future strategies to reduce the risk of relapse post-transplant. How these agents affect the overall toxicity in HCT is currently unknown.

Comorbid conditions

The need for a careful history and a physical examination, and also objective tests that allow for a determination of the patient's organ functions, must be stressed. In addition, regimen-related toxicity remains an important issue for all candidates for autologous HCT who will be exposed to maximum tolerated doses of chemotherapeutic agents (with or without radiotherapy).

A pre-HCT specific comorbidity index (HCT-CI) has been developed and validated [43,58]. In these retrospective analyses, patients with a low score (0), intermediate score (1–2), and high score (≥3) had a 2-year cumulative incidence of NRM of 7, 19–21, and 27–37%, respectively. The components of the HCT-CI are summarized in Table 29.4. General eligibility criteria for adult candidates for allogeneic or autologous HCT are described in Table 29.5. Below, some of the most important aspects of compromised organ function are discussed.

Table 29.5 General eligibility criteria for adult candidates for allogeneic or autologous HCT

Criterion	Allogeneic HCT	Autologous HCT
Age	No strict age cut-off	No strict age cut-off
Karnofsky performance score	70–100 for high dose ≥50 for reduced dose	70–100
Left ventricular ejection fraction	>35%	≥40% BEAM, ≥50% cyclophosphamide
Pulmonary function test; forced vital capacity	≥60%	≥60%
Diffusion capacity (DLCO)	≥35%	≥50%
Kidney function	≤2 mg/dL	≤2 mg/dL, unless for myeloma
Liver function	No cirrhosis	No cirrhosis
Mental health	Adequate psychosocial and financial support	Adequate psychosocial and financial support

Cardiac evaluation

Patients over the age of 50 years or those with a history of extensive exposure to anthracycline drugs may be at risk for future cardiac complications, especially if high doses of cyclophosphamide are part of the planned conditioning regimens [59–61]. In our experience and that of other centers, life-threatening cardiotoxicity after HCT is rare, occurring in less than 2% of all transplant recipients [62]. An ejection fraction of less than 50% as measured by two-dimensional echocardiography and a prior history of congestive heart failure are significant independent correlates of clinical cardiotoxicity [63]. Many cooperative cancer research groups and also some insurance companies insist on the use of radionuclide tests of ventricular function as a requirement for the enrollment of patients to clinical transplant trials or for the authorization of financial coverage, respectively. There is little reason to insist that all transplant candidates be evaluated with multigated acquisition scans [64]. Considerable financial resources can be saved by relying on two-dimensional echocardiography (if indicated with a stress echocardiogram). Additional advantages of a two-dimensional echocardiogram include the ability to evaluate for evidence of valvular disorders, and this may be a preferred test in patients with a history of valvular disorders or an abnormal cardiac examination. Retrospective studies performed in MDS and AML indicate that there are some patients in whom cardiac evaluation preinduction chemotherapy is not warranted [65]. Studies evaluating the necessity of radiographic cardiac evaluations in the pre-stem-cell transplant population are lacking.

Respiratory evaluation

Pulmonary function tests (PFTs) such as the forced expiratory volume, forced vital capacity, and diffusion capacity have gained a firm place in the pre-transplant evaluation of HCT candidates [66–70]. A decrease in these parameters before HCT predicts for post-transplant respiratory impairment, especially if chronic GVHD occurs, in both children and adults [70]. The data regarding the utility of PFTs are not as clear in recipients of autologous grafts [71]. Recent data have indicated that PFTs alone should not be used to exclude patients from a stem-cell transplant but should be considered as part of an overall assessment of comorbidities [72].

Hepatic evaluation

Liver function tests are routinely obtained before and after marrow HCT in an attempt to predict or detect hepatic compromise. An elevation of transaminases at the time of admission for HCT was significantly associated with post-transplant hepatic sinusoidal obstruction syndrome (SOS). Other risk factors associated with this complication included vancomycin therapy during cytoreductive therapy, acyclovir therapy before HCT, administration of gemtuzumab ozogamicin, and radiation therapy to the abdomen at any time before HCT. The incidence of SOS after HCT varies greatly among transplant centers, ranging from less than 2% to over 50% [73,74]. Possibly, patient selection and donor–recipient matching, and also tight control of the patient's fluid status, may play an important role in the occurrence or prevention of this syndrome. The incorporation of ursodeoxycholic acid as a prophylactic strategy post-transplant has reduced the incidence of hepatic SOS [75].

Renal evaluation

Testing of renal function is a standard requirement at all HCT centers. Serum creatinine of under 1.5 mg/dL (for adult patients) and a creatinine clearance over 60 mL/min are considered adequate as eligibility criteria for transplant candidates. Considering the potential nephrotoxicity of several drugs that are frequently used after HCT, such as calcineurin inhibitors, vancomycin, foscarnet, and other agents, adequate kidney function is an important component of the pre-transplant assessment. However, there are some patients who have successfully undergone allogeneic HCT while dialysis-dependent at our center. However, in patients with multiple myeloma who are treated with high-dose melphalan and autologous HCT, even highly abnormal kidney function may still permit a successful transplant outcome [76], and there are some patients with renal failure due to multiple myeloma who have improvement in renal function following HCT [77]. Although dialysis dependence is not an absolute contraindication to HCT, the development of renal failure following HCT is associated with an increased risk of mortality [78].

Nutritional status

A nutritional assessment by an experienced dietitian, including an exploration of the patient's dietary habits, should be part of the evaluation process of each transplant candidate; for details, see Chapter 99.

Extreme nutritional conditions such as cachexia or morbid obesity require special considerations and counseling. Malnourished patients may require pre-transplant enteral or parenteral nutrition to improve their general condition, and patients suffering from excessive obesity may be advised to reduce their body weight under the guidance of a dietitian – provided that the underlying disease permits the delay of the transplant procedure.

It has been demonstrated in a large clinical study of 2238 patients at the Fred Hutchinson Cancer Research Center that body weight impacts on NRM after allogeneic HCT [79]. This analysis indicated that patients whose actual body weight (ABW) ranged between 95% and 145% of ideal body weight (IBW) experienced comparable NRM, whereas patients whose weight was less than 95% or above 145% had decreased survival. The treatment outcome was poorest in patients whose ABW was less than 85% of ideal body weight (IBW). A similar analysis was made at Stanford University School of Medicine in 473 consecutive adult patients with hematologic malignancies who received high-dose combination therapy followed by autologous HCT. Again, those patients who were malnourished or those who were extremely obese fared the worst [80].

The dosing of drugs in the preparatory regimen is frequently adjusted to IBW, which may be considerably different from the patient's ABW. In the case of very obese patients, this dosing policy would result in serious underdosing with all its inherent consequences, such as insufficient immunosuppression and decrease in tumor cell kill. To overcome this problem, some transplant centers have made provisions in their clinical protocols by using a formula to calculate an adjusted IBW, namely, IBW plus 50% of the difference between ABW and IBW. For example, if a patient's IBW is 80 kg and the ABW is 130 kg, then the adjusted IBW would be 105 kg. Similar calculations apply if the patient's body surface is used to determine drug doses.

For several drugs (busulfan, cyclophosphamide, and others), pharmacodynamic monitoring is more meaningful for dose decisions than is body weight (see Chapter 19).

Comorbidity assessment

The assessment of pre-transplant patient-specific factors to determine post-transplant outcomes is an area of ongoing research. Several different risk assessment systems have been published. The three most commonly used systems are the European Society for Blood and Marrow Transplantation (EBMT) risk assessment score [81], the pretransplant assessment of mortality (PAM) score [82], and the hematopoietic cell transplantation-specific comorbidity index (HCT-CI) [58]. There have been few studies that compared these risk assessment models. One study compared the HCT-CI with the PAM risk score and found that the HCT-CI was the best predictor of NRM [83]. In addition, there have been studies validating the HCT-CI in external cohorts [84]. One major issue in the application of these systems is the inter-rater reliability, which can be fairly high [85]. The components of the HCT-CI are summarized in Table 29.4. Ultimately, prognostic models in the future will involve the conflation of patient-specific and disease-related risk factors [86,87].

Age of the transplant candidate

Age of allogeneic HCT candidates

During the early years of allogeneic HCT, successful outcome was limited mostly to children, adolescents, and younger adults. In 1986, two groups reported encouraging results after high-dose therapy and allogeneic marrow HCT in older adults, aged 32–54 and 45–68 years, respectively [88,89]. The issue of age and eligibility for HCT is particularly relevant for diseases such as MDS, where there is a clear association between increasing age and development of the disease. Retrospective reviews have indicated that patients aged up to 65 years are able to tolerate high-dose conditioning with the use of related donors [90]. Additionally, post-transplant outcomes do not appear to be related to age or the intensity of the conditioning regimen but rather the disease stage at time of HCT [91].

The arrival of less toxic, reduced-intensity regimens has allowed the extension of allogeneic HCT to patients in the age group 60–75 years [34,38,92,93]. A retrospective analysis from the Center for International Blood and Marrow Transplant Research (CIBMTR) in patients with MDS or AML aged 40 years or more indicated that age alone did not have a significant impact on overall outcomes following reduced-intensity HCT [42]. A similar study in our center in 372 patients aged 60–75 years with a variety of hematologic malignancies showed no impact of age on overall survival, NRM, progression-free survival (PFS), or the incidence of acute GVHD [94]. The 5-year overall survival and PFS were 35% and 32%, respectively. This further highlights the concept that consideration for stem-cell transplant should be based on overall measures of comorbidities rather than specific singular factors.

Age of autologous HCT candidates

Several transplant centers have analyzed the effect of age on the outcome of autologous HCT [95–99]. Although there appears to be an increased risk of NRM during the early phase after HCT in patients over the age of 50 years, it does not seem to be warranted to exclude older patients from autologous HCT. The majority of the data regarding age and post-transplant outcomes is derived from patients with a diagnosis of multiple myeloma [99–101]. A retrospective analysis in patients who underwent autologous HCT for lymphoma indicated that age alone should not serve as a contraindication [102] .

Ethnicity, race, and socioeconomic issues

Decisions regarding the beneficial role of HCT must take into account the overall circumstances of an individual patient. These also include psychosocial aspects. The living environment certainly plays a role in whether patients have a successful outcome with HCT, in addition to other socioeconomic factors such as access to good dental and medical care prior to HCT. In a retrospective analysis of 6207 individuals who underwent high-dose conditioning followed by unrelated donor HCT, overall survival was worse in patients from a lower socioeconomic status. This decreased overall survival was primarily attributable to a higher treatment-related mortality, thus implying that non-disease-related factors are important determinants of post-transplant outcome and that these non-disease-related factors are at least in part attributable to socioeconomic status [103].

There are multiple issues that contribute to the availability of HCT based on race and ethnicity. Socioeconomic factors certainly play a role in both the autologous and allogeneic setting. However, there appears to be greater disparity in the allogeneic setting potentially attributable to donor availability [104]. Numerous studies have dealt with the effect of race on the outcome of autologous or allogeneic HCT [103,105–108]. With respect to autologous HCT, race and ethnicity were not significantly associated with survival of 1366 patients [105]. Analyzing the outcome of 2221 recipients of allogeneic grafts from histocompatible siblings indicated that patients of African American background had a significantly greater mortality than white patients [106]. HCT was more associated with severe acute GVHD, and NRM was higher among African American than white patients, presumably as a result of increased HLA mismatching or genetic polymorphisms that affect drug delivery. The increasing use of cord blood stem cells will likely impact this disparity in a positive manner. Mortality among other racial and ethnic groups was not significantly different from that of white patients. In another study on 1752 recipients of grafts from histocompatible siblings, it was found that white Americans, African Americans, and Irish cohorts were at significantly higher risk for acute GVHD than Japanese or Scandinavian cohorts, indicating that there may be more HLA disparity in white Americans, African Americans and Irish cohorts compared with Japanese and Scandinavian cohorts [107]. Despite the increased risk of acute GVHD, there was no difference in overall survival. The increasing use of cord blood cells as a stem-cell source will likely address some of the racial disparities regarding access to HCT [109], but socioeconomic factors will likely continue to play a role in post-transplant outcomes.

Previous infections

Beginning with the time of their initial diagnosis, patients enter a phase in their treatment when they become more susceptible to infections than healthy individuals. Their conditions are even more compromised by antineoplastic treatments with chemotherapy and/or irradiation or, in the case of marrow failure, exposure to immunosuppressive drugs such as cyclosporine, antithymocyte globulin, or glucocorticosteroids. Many of the patients referred to transplant centers have a history of prior infections with bacteria, fungi, or viruses [110]. Modern medicine has provided us with powerful antimicrobial drugs, which is one of the factors that led to improved survival following HCT [111,112]. Preemptive strategies with ganciclovir to prevent cytomegalovirus (CMV) disease have dramatically reduced CMV infection as a cause of post-transplant mortality [113]. Randomized phase III trials have failed to show a significant reduction in overall outcomes in patients who receive preemptive therapy with the new azole compounds as compared with fluconazole [114,115]. A meta-analysis indicated that the routine use of polyvalent intravenous immunoglobulin (IVIG) post-transplant does not decrease infectious complications following HCT [116]. Additionally, the use of polyvalent IVIG was associated with an increased risk of hepatitis SOS/venocclusive disease (VOD).

The evaluation of transplant candidates, in particular those who are scheduled to undergo allogeneic HCT, should include a meticulous search for any signs of subclinical infectious sources. Such studies include standard X-rays and, if clinically indicated, computed tomography (CT) and magnetic resonance imaging (MRI) scans [117]. A prospective study has shown that the underlying disease and leukocyte count are associated with the ability to isolate fungal organisms in respiratory samples obtained via bronchoscopy [118]. In addition, a dental examination is recommended and corrective dental procedures should be performed prior to transplant if possible given the underlying disease and donor availability.

Infections with HIV, hepatitis B, or hepatitis C are not contraindications for either autologous or allogeneic HCT [119]. Certainly, patients with these underlying infections are at increased risk of reactivation following transplant. Concerning specific infections, the reader is referred to Chapters 85–93.

Transfusion history

For those patients who have been transfused, a detailed transfusion history should be obtained, namely, number of and response to red blood cell and platelet transfusions. In addition, patients should be questioned about the use of granulocyte transfusions as they may lead to increased HLA sensitization. It is also important to monitor the number of transfusions in order to assess cumulative iron load. Elevated serum ferritin levels are strongly associated with lower overall survival and DFS in patients transplanted for AML or MDS [120]. Ferritin is a poor marker for iron overload given its role as an acute phase reactant. For that reason, some have questioned the legitimacy of using ferritin as a marker for iron overload in patients undergoing HCT. Indeed, a recent analysis indicated that patients who have iron overload as measured by MRI of the liver are not at increased risk of mortality following HCT [121]. Additional retrospective studies showed an association between transfusion dependence and increased comorbidities prior to HCT [122], which may explain the increased mortality observed post-transplant. Recent studies indicate that many long-term transplant survivors have secondary hemosiderosis and may need iron mobilization therapy [123].

Psychosocial assessment

It is the goal of the psychosocial assessment to get to know candidates' personalities and related issues in order to maximize patients' participation in their own care and to lay the foundation for a successful return to their personal and professional life after HCT. It is furthermore the goal to minimize problem areas that would interfere in any way with the transplant procedure and the recovery phase. Pretransplant family conflicts are among other factors associated with impaired medical and psychosocial recovery [124]. A patient's psychosocial history and condition have the potential to enhance or detract from the transplant procedure. The assessment, including an evaluation of previous response to pain control, should be made by a qualified professional at the time the patient's medical candidacy is being evaluated. In addition, appropriate insurance funding for HCT is part of the evaluation process. The purpose of the psychosocial assessment is summarized in Table 29.6.

Substance abuse is associated with a poor outcome of HCT [125], and uncontrolled drug, nicotine, and alcohol dependences are exclusion criteria. Several studies have demonstrated an association between NRM and smoking [126,127]. A history of any substance dependence indicates the need for a formal psychiatric evaluation prior to acceptance for HCT. Since there is an association between poor pre-transplant executive functioning and risk for post-transplant delirium, steps should be taken to ensure that patients with lower executive functioning have appropriate monitoring and intervention at the first sign of impairment [128]. Adherence to post-transplant guidelines has been assessed in a prospective survey [129]. Non-adherence was associated with poor knowledge and concerns about medical costs. Therefore, it is important that patients be appropriately informed regarding the importance of medical compliance and that healthcare costs are adequately addressed during the initial and ongoing visits.

Several of the issues mentioned with psychosocial assessment overlap with what has been stated in earlier paragraphs describing the patient–physician interaction. It is desirable that some of the psychosocial issues be assessed by more than one person, i.e. the attending physician and the medical social worker. The impression of both examiners should be presented in a formal meeting in order to create an impression of the patient's candidacy for HCT. During such a meeting, all medical and social issues should be presented to an institutional group of transplant physicians, social workers, research nurses, dietitians, and so on, and the candidacy for HCT of the referred patient, including enrollment in institutional or national clinical trials, be determined.

Table 29.6 Goals of the psychosocial assessment of adult HCT candidates

Purpose of psychosocial assessment:

1. Documentation of psychosocial stability
2. Identification of patient and family strengths and weaknesses in coping mechanisms
3. Assistance with preplanning for the HCT procedure, e.g. arrangement for childcare, transportation, state and Federal program linkages
4. Coordination of any corrective action, if necessary, for the success of the transplant procedure, e.g. referral for psychiatric evaluation, compliance contract, drug testing

Individual areas of patient assessment should include:

1. Previous methods of dealing with treatment issues and crises
2. Past and present drug, alcohol, and tobacco usage
3. Past and present psychiatric history
4. Understanding of diagnosis, treatment plan, and prognosis
5. Compliance with previous therapy needs
6. Motivation
7. Unique cultural, religious, literacy, and language needs
8. Ability to use information given
9. Previous activity and interest levels

Other important areas for assessment:

1. Emotional support for the patient during all phases of HCT
2. Caregiver availability, i.e. family members or friends
3. Employment issues
4. Advanced care directives, e.g. durable power of attorney for health care, a will
5. Stability of the environment to which the patient is expected to return
6. Family adjustment to diagnosis, therapy, and prognosis
7. Ability to relocate geographically for HCT
8. Other stressors, e.g. parents, children, insurance, transportation

Special considerations for pediatric transplant candidates

The matter of consent

Obviously, many of the medical and psychosocial concerns of the adult HCT candidate are pertinent to children, but because the patient is a child, the physician must also attend to the concerns of the patient's guardian(s). Foremost among these concerns is the matter of consent.

Whereas for adult HCT candidates the impact of HCT on a spouse and other family members must be considered, ultimately the patient, informed of the risks and benefits of HCT, consents to treatment. Children and adolescents are not legally able to consent. The primary caregiver, usually the parents, on behalf of the child must weigh the options and decide the best course. Providing parents with information and direction and helping them reach an appropriate decision for their child is the role of the physician. It also important to involve the adolescent in the decision-making process as well. At our institution, we use simplified assent forms for young children (aged 7–13 years) and regular consent forms for teenagers (aged 14–17 years). In both circumstances, we also obtain consent from the parent or legal guardian. This process allows for some feeling of control from the adolescent and the young child and also keeps them involved in the decision-making process.

Initial visit by the patient and parents

The patient, be it an infant, young child, or adolescent, is the physician's primary concern. Although the parent or legal guardian signs the informed consent, the physician must be attuned to the patient's capacity to understand the transplant process. Young children, precocious in the understanding of their disease and its implications, require an explanation of HCT rationale suitable to their level of comprehension. Alternatively, adolescents who do not choose to be involved in decisions regarding their treatment should be allowed to participate up to their level of comfort. The physician must grasp the child's emotional maturity and provide an appropriate level of treatment discussion. Parents may be helpful in advising the physician of the patient's desires, although some parents, irrespective of the child's wants, seek to protect the patient from knowledge of the serious risks and consequences of treatment.

Children with malignant disease

Whether a child is a candidate for an allogeneic or autologous HCT depends upon the disease diagnosis and status. Depending upon the circumstances, the initial family conference must clarify the rationale for HCT. It happens that parents arrive at this meeting with preformed impressions and fears, which have arisen from conversations with other parents or with family and friends. Often what parents have heard is erroneous or exaggerated, and these notions must be corrected.

The indications for HCT for children with malignant disease continue to evolve just as they do for adults. Where opinions differ regarding the necessity for HCT, it is important to discuss the alternative treatment with the parents. In centers where physicians limit their practice to HCT patients, the obligation regarding counseling families differs from centers where the physician is responsible for managing both the standard chemotherapy and HCT. In the former, a primary physician has determined that HCT should now be considered an option and refers the patient. Although the transplant physician must decide based upon his or her own understanding whether HCT is appropriate for the child, there is no inherent conflict between the treatment roles. In centers where roles overlap, the physician must be aware of potential bias and carefully explain the treatment alternatives, even offering the family the option of a second outside opinion.

Children with non-malignant disease

Although children with malignant disease comprise the majority of transplant candidates, patients with genetic and immunologic disorders may benefit from HCT, and these patients and their families require that the consent discussion be attuned to the specific disease. Non-malignant diseases eligible for HCT include conditions that are immediately life threatening, for example, aplastic anemia or severe combined immunodeficiency, and other conditions that, although not immediately life threatening, ultimately will lead to death or to devastation of the child's quality of life, for example, sickle cell anemia or adrenoleukodystrophy.

When patients are referred for HCT for these indications, it is critical that the transplant physician works closely with the primary specialist. Ideally, a coordinated effort will accurately portray the intent for HCT and what might be achieved. It also lays the groundwork for the patient's optimal care in the post-transplant setting. Even when HCT is successful, there may be delayed toxicities from therapy, or patients may remain susceptible to elements of the primary disease. Coordination of care is essential to maximize the transplant recipient's quality of life.

Patients with non-malignant disease rarely receive chemotherapy prior to HCT. Without this experience, patients and families lack a frame of reference to comprehend the side effects, both expected and rare, that may occur during HCT conditioning therapy. The physician must carefully explain the necessity for conditioning therapy and reassure families that all efforts will be taken to minimize discomfort and risk for their child.

Conditions affecting the child as a candidate for HCT

The evaluation of the patient as an HCT candidate reconciles the patient's current state of disease and overall physical condition. Both elements influence treatment outcome and prognosis. Occasionally, circumstances arise where there is no longer any benefit for HCT. In such cases, outside a clinical investigation, the recommendation should be against HCT. Initially, for most families this will be unacceptable, but with a careful and compassionate explanation, the physician can bring the family to understand that the discomforts and toxicities of HCT are not justified for their child when there is no benefit.

More difficult for the patient, family, and physician are those circumstances where the likely benefit from HCT is low but not altogether absent. Here too, candid discussion allows the family an opportunity to ask questions and discuss their concerns and expectations. Although it is rare that the family will decide not to proceed with HCT, knowing that refusing HCT is an option can be very important. It is possible that an older adolescent may refuse HCT or wish to delay hospital admission to fulfill an important life wish. These decisions, whichever way, should be respected and supported by the physician.

Table 29.7 The Lansky play-performance scale [130] (for use with persons aged 1–16 years)

Score (%)	Description
100	Fully active, normal
90	Minor restrictions in physically strenuous activity
80	Active, but tires more quickly
70	Both greater restrictions of and less time spent in play activities
60	Up and around, but minimal active play; keeps busy with quieter activities
50	Gets dressed but lies around much of the day, no active play; able to participate in all quiet play activities
40	Mostly in bed; participates in quiet activities
30	In bed; needs assistance even for quiet play
20	Often sleeping; play entirely limited to very passive activities
10	Unresponsive
0	Dead

Estimation of performance status is always subjective to some extent, and this applies even more so for children compared with adults. The Karnofsky scale, intended for adults, can be used for older children; school serves as a surrogate for work. For younger children, the Lansky scale (Table 29.7) [130] is more appropriate, but this scale relies heavily on parental reports. Even more problematic, the scale includes developmental skills that are not applicable to toddlers and infants. Although it has been demonstrated that pre-transplant performance measure may correlate with outcome, alone these scales lack sensitivity and specificity sufficient to counsel the family. Combined with organ-specific evaluations, performance scale measures can identify patients at greater risk for regimen toxicity [131,132].

For children with malignant disease, the most likely explanation for a low performance status is the effects of the disease for which HCT is being considered. Children have not lived long enough to suffer the morbidities that arise from aging and/or a lifetime of bad health habits. Organ-specific evaluation must anticipate the consequences of prior therapies, for example, myocardial injury secondary to anthracyclines or mediastinal irradiation. Complications from prior therapy may be exacerbated during the transplant course, as a patient with previous pulmonary fungal disease and reduced respiratory reserve is at grave risk from further lung injury. The physician's exposition of the performance status, organ evaluation, and prior morbidities enables the patient and family to comprehend better the risks undertaken during HCT and to understand the rationale of the treatment plan.

Organ system evaluation for the pediatric patient is similar to that for an adult but, depending upon the child's age, may require modification. For the youngest patients, pulmonary function tests may not be available [133]. Some children's hospitals can perform pulmonary function tests on infants, but their value in the transplant setting has not been established. If a child has experienced serious respiratory complications, imaging studies and consultation with a pediatric pulmonologist prior to transplant may be useful.

Two potentially important conditions, obesity and iron overload, may increase the risk for regimen-related toxicity, particularly liver toxicity. The increase in morbidity and mortality associated with excess liver iron has been established for patients undergoing HCT for thalassemia, but undoubtedly this association is pertinent to any patient with iron overload [120]. Thus, any child coming to transplant having received frequent red cell transfusions, for example, a patient with Diamond–Blackfan anemia or other marrow failure disorders, must be considered at heightened risk from regimen-related toxicities. Although iron accumulation by the heart can compromise cardiac function, adequate cardiac function determined by echocardiography diminishes the likelihood of clinically significant iron accumulation.

Poorly nourished children coming to HCT can usually be managed successfully with parenteral nutrition; less apparent is the risk for toxicity that HCT imposes on the obese child. For obese patients, elevated liver transaminase may be indicative of liver steatosis, or of steatohepatitis when insulin resistance and hypertriglyceridemia are also present [134]. The metabolic syndrome of obesity, hypertension, hyperlipidemia, and glucose intolerance is causally related to cardiovascular disease in adults, but the significance of these findings has not been established for children. It should be noted that children, particularly adolescents, are more prone to the hyperglycemic effects of prednisone and L-asparaginase [135]. Parents and caregivers compound the problem by ignoring or even promoting obesity by allowing the child indiscriminate amounts of high-calorie food.

The impact of HCT on the child's neurocognitive development concerns parents and physicians alike. If possible, neurocognitive testing should be obtained for all children before the start of conditioning [136]. Baseline assessment provides a reference to measure future development, which becomes important if remediation efforts are needed later. This is most relevant for children who receive TBI and/or CNS irradiation for conditioning, as such patients are most at risk for neurocognitive injury. Neurocognitive tests are absolutely essential to evaluate patients with metabolic storage disorders that cause neurocognitive deterioration. Poor neurocognitive performance index prior to HCT predicts an unsatisfactory outcome following HCT and should dictate against proceeding [137].

Counseling the patient and family

Emotional distress for patients undergoing HCT often is most severe as treatment commences and tends to diminish thereafter [138,139]. Likewise, parents' distress prior to HCT is greater than at any later time during the transplant course [140]. Therefore, the initial meeting with the family should attempt to address the causes for their distress. Not knowing what to expect from HCT is a major source of anxiety and fear. The physician, by providing details of the transplant course, allows the child and family to participate in and, to some extent, to control future events, which can help diminish stress. Additional consideration should be given to the parents' coping strategies and also the family environment, as a prospective study has shown that these factors are related to distress in children prior to HCT [141]. The dynamics of the family and specifically the parents sometimes affect the child/patient in a detrimental manner.

The discussion of medical matters should be tailored in a manner that is appropriate to the cultural and social background of the family. Although it is important to convey the rationale for HCT in addition to its risks, benefits, and long-term consequences, the discussion must ultimately meet the needs of the patient and the family. Some families prefer very detailed information and may even question the necessity for particular elements of the treatment, for example, the use of TBI. Yet other families become confused and anxious from too much detail and prefer to place their trust in the physician and be reassured that the physician will do the best for their child. If desired, other family members should be allowed to partake in the consultation process. Single parents, overwhelmed by the total responsibility for consenting, should be encouraged to bring a grandparent or other supportive person to this meeting [142]. If the treatment is a clinical trial, the physician must take care that the patient and family understand the experimental component, possible alternative treatments, and their right to refuse or withdraw [142]. The presence of a child life specialist at the consent discussion may be an effective means to assure understanding of the proposed treatment.

Every family brings hope for the future of their child to the HCT process. HCT is the means to the future, and at that moment the parents' focus is on the child safely passing through this treatment. Nonetheless, there are important long-term consequences arising from HCT of which parents must be made aware. Among these are the effects of HCT on intellectual development, growth, and fertility, and the risk for a second malignancy following HCT [143].

Problems arising from school are not uncommon for children post-HCT. Undoubtedly, patients come to transplant already challenged academically because of the school absence related to the primary disease and its treatment. Certain diseases for which HCT is performed may directly impact the CNS, such as brain tumors or demyelinating diseases. For hematologic malignancies, previous treatment, including intrathecal chemotherapy, may have affected neurocognition. HCT conditioning therapy with TBI adds to the risk for future learning difficulties, although it has been shown that cognitive function does not invariably decline post-HCT. Reassuringly, except among the youngest patients, many studies find preservation of pre-HCT neurocognitive function [136,144]. For children less than 3 years of age, most investigators document at least some fall-off in neurocognitive test performance. In relaying this information to parents, it is important to emphasize that a profound deterioration of intellect is rare and that coordinated efforts between neuropsychologists and educators may help the child compensate.

Linear growth depends upon intact bone and endocrine function; radiation therapy disturbs both systems. As is true for neurocognitive function, the patient's growth may have suffered prior to coming to HCT, and again it is the youngest patients who will be most seriously affected [145,146]. The physician must counsel the parents that while treatment with growth hormone may improve the child's linear growth, it is unlikely that the child will achieve what would have been the predicted adult height (see Chapter 102).

Although fertility has been discussed previously, there are several points unique to pediatric patients. Pubertal development may be delayed in up to half of children treated with fully ablative conditioning, and children receiving fully ablative HCT conditioning, particularly when the conditioning includes TBI, rarely are fertile [145]. For patients with malignancy and previously treated with intensive chemotherapy, fertility may have already been diminished. Often families indicate that they had not been aware of this possibility. Even as parents learn of and accept the risks for regimen-related toxicity and the potential for unfavorable or even fatal outcome following HCT, it may be heartbreaking for some to have to accept the responsibility for their child's infertility. For many cultures, the loss of the ability to conceive carries momentous impact, and the physician must be attuned to this. The development of reduced-intensity conditioning therapy may allow more children to retain their fertility, and the potential for advances in reproductive medicine offers parents hope for the future [147].

Successful HCT allows children the chance to live a normal and meaningful life but, unfortunately, not a life without persistent concerns. One undesirable consequence of surviving is the risk of secondary cancer. The risk is, in part, disease and HCT conditioning regimen specific [148]. Unfortunately, the risk of secondary cancer has not been adequately determined for every condition. HCT conditioning therapy that includes radiation has been associated with a higher incidence of new tumors, but heightened risk exists for patients receiving chemotherapy alone [149]. It may be important to note here that the estimate of developing solid tumors was 13% among patients transplanted for aplastic anemia and that, in the multivariate analysis, radiation, typically less than 10 Gy, was associated with that increased risk [150]. Although reduced-intensity conditioning regimens allow children with severe pre-transplant morbidity to undergo HCT, the risk for secondary cancers from reduced-intensity regimens has not been defined.

Advanced care planning (ACP)

HCT is an aggressive and intensive treatment and is intended to be life saving; however, it is associated with short-term morbidity and mortality. Physicians should establish during the initial sessions that other aggressive interventions, for example, dialysis or mechanical ventilation, may be needed to support the patient during the treatment course [3]. Discussion of ACP offers adolescents and some precocious younger children and their parents an opportunity to consider in what circumstances the decision would be to withhold or withdraw care. Rarely do adolescents provide an advanced directive; however, these matters may be discussed within the family, and parents will know of their child's wishes. These conversations will become very important should care ultimately become futile. Unfortunately, only 50% of adult transplant recipients are engaged in ACP. A retrospective survey indicated that patients who are not engaged in ACP have an inferior outcome compared with patients who are engaged in ACP [5], thus indicating that the patients who did not engage in ACP were the very patients who were most likely to need it.

Some final considerations

HCT requires a cooperative, educated, and insightful patient. Through the educational efforts of the transplant team and the informed consent process, the patient should have acquired the high level of understanding and knowledge that is a prerequisite for participation throughout the long HCT process, both at the transplant center and subsequently in the domestic environment. It is sometimes forgotten or ignored that the transplant process is not completed with the return of the white blood cell count to the normal range. Deficiencies of the immune system persist for many months and sometimes years following HCT.

Allogeneic marrow graft recipients especially are at risk for late infectious complications even if all in vitro tests are showing a return of normal immune function. The transplant patient should be instructed to seek medical advice for even relatively harmless-appearing symptoms. A well-functioning communication system between the transplant center, the patient, and the local physician has to be a permanent part of the post-transplant course. Most major transplant centers have a long-term follow-up department that assists local physicians caring for the post-transplant patient. It is important that the lines of communication between the local physician and transplant center remain intact. Patients serve as an important component of that link and they should always be encouraged to contact the transplant center if there are any complaints which they feel are not being adequately addressed by their local physician.

This chapter can never be complete. There are simply too many medical or social circumstances that cannot be described in detail or even be anticipated. There are no rules for common sense and no substitute for professional judgment or rapid communication.

CHAPTER 30

Nursing Role in Hematopoietic Cell Transplantation

Rosemary C. Ford, Mihkaila M. Wickline and Diane Heye
Seattle Cancer Care Alliance, Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Introduction

Caring for patients undergoing hematopoietic cell transplantation (HCT) is one of the most challenging and rewarding of all nursing subspecialties. These patients require nurses with expertise in assessing the acute, subtle, and unique clinical changes of HCT. In addition to the knowledge base of oncology nursing, the specialty of HCT nursing requires expertise in addressing unique diseases such as sinusoidal obstructive syndrome (SOS) and graft-versus-host disease (GVHD). Most of nursing's effort is focused on the post-transplant phase with managing side effects and toxicities, and preventing complications caused by the high-dose chemoradiotherapy given to prepare for HCT and the consequences of GVHD [1]. Nurses are the members of the HCT multidisciplinary team who spend the most time with the patients, and often are the first to identify changes in clinical status. Nurses must also have psychosocial skills as they support the patients and their significant others through decisions and acute clinical changes encountered during the HCT process [2].

Supporting medical research, the foundation of HCT care, is another factor that attracts nurses to this subspecialty. Integrating new research initiatives into clinical care and being on the front line as new therapies evolve to change standard practice are very exciting. Nurses experience satisfaction from working in a medical arena offering the best possible therapy to their patients. Those nurses who stay with this specialty over a number of years witness therapies used in phase I research studies become the standards of care or the basis for future research. These nurses can readily identify the improvements in patient outcomes that have occurred in the field of HCT over the past three decades in curing specific diseases, and also improvements in the prophylaxis and treatment of GVHD and SOS, infectious disease prevention and therapy, and symptom management. In addition, expanding HCT to treat autoimmune diseases and solid tumors has required nurses to become familiar with disease processes beyond hematologic malignancies. Treating patients using reduced-intensity conditioning regimens has presented new challenges to HCT nurses. Not only are these patients often older with more comorbidities than those eligible for myeloablative regimens, but also the patterns in their clinical courses in areas such as acute GVHD presentation can differ from those of myeloablative transplants. Nurses must be flexible and able to accommodate changes in medical therapy such as extracorporeal photopheresis for the treatment of chronic GVHD [3]. Another example is the recent increased use of umbilical cord transplants to expand the pool of patients able to be treated, which challenges nurses with a different level of immunosuppression experienced by these patients.

There has been a shift in the site of HCT care from inpatient units to outpatient infusion treatment facilities and clinics with the goal of containing costs while maintaining high-quality, safe patient care [4,5]. These changes were made possible by major improvements in oral antiemetic efficacy, antibiotics with less frequent dosing, and improved ambulatory infusion devices. Patients can receive all of their conditioning and hematopoietic stem cell (HSC) infusion in an outpatient setting, and are admitted only as their clinical picture dictates (usually fever or mucositis pain). Patients are also discharged from the hospital based on more liberal criteria than in the past. This change has resulted in increasingly complex ambulatory patients where the focus of nursing care shifts from first-hand assessment and care of inpatients to teaching the caregivers to provide some of these skills in the home setting [6]. This has resulted in the average acuity of the HCT inpatient populations to be markedly increased, with patients acutely ill with complicated multisystem issues. It has also led to the majority of patients having multiple unscheduled admissions and discharges in the months after transplant. Nurses are responsible for ensuring continuity of care and patient safety as the responsibility for care is handed off from one site to another [7].

The intensity of therapy requires subspecialization of HCT nurses to meet the care needs of these patients [8]. Transplant centers organize nursing support in a variety of ways depending on their larger operational structure. At most centers, specific nurses, or "coordinators," have a role in the initial intake of patients into the program. Most outpatient clinics have a case manager structure, which allows for continuity of care coordination throughout the transplant process. HCT patients often spend large amounts of time in outpatient infusion areas. These patients require nursing expertise different from that of other oncology outpatients. Inpatient care is provided either on a specific transplant unit or on a hematology–oncology unit. Each center needs to give serious consideration regarding whether to keep HCT patients requiring intensive care on the HCT unit or to transfer them to an intensive care unit (ICU). In either case, nurses with expertise in both HCT and intensive care are required. Discharging HCT patients from an inpatient unit to the outpatient setting is often complex, especially with more liberal discharge criteria, and many centers have specific nurses with expertise in managing these transitions[9].

Complex research protocols often require coordination by a nurse who works closely with the principal medical investigator.

These nurses are responsible for ensuring documentation of protocol data and the reporting of adverse advents. They are key in ensuring that protocol coordination is seamless when patients transfer to and from the inpatient and outpatient settings. They are the primary resource for medical and nursing staff regarding protocol implementation. In addition, because of the relatively long length of stay in the medical centers with standardized treatments, HCT patient care provides ideal opportunities for nursing research. Nursing studies have been conducted in a number of areas including quality of life and symptom management [10–15].

The purpose of this chapter is to describe the nurse's role at the various phases of the HCT process. Tables detail the key specific nursing responsibilities of assessment, teaching, care coordination, and carrying out the medical care plan at each phase.

Assessment includes evaluating not only the basics of physical assessment of the patient, but also the ability of the patient and caregivers to cope with this intense experience.

Teaching must be individualized to each specific patient and caregiver situation. There is no substitute for one-on-one assessment and teaching by the patient's primary nurse. One-on-one encounters allow for assessment of the patient's assimilation of the required information and a time for the patient to ask whatever questions are of foremost concern. Teaching can be accomplished by a variety of methods, including written materials with photographs or illustrations and electronic learning formats. Classes are also an effective initial teaching method, followed by individual instruction for centers that perform a large number of transplants.

Coordination of care for these patients is extremely complex and critically important. Nurses assess the patient's and family's strengths and weaknesses, and plan interventions to assist them to integrate this intense therapy into their lives. Nurses must include clinical issues, operational resources, research requirements, and the patient's abilities, needs, and desires when planning care.

Carrying out the medical care plan is an important role of the transplant nurse. Specialized understanding of the patient's underlying illness, the transplant procedure, complications of transplant, and the typical treatments for each complication are important for successful implementation of the medical care plan.

Prework-up/prior to arrival at the transplant center (Table 30.1)

The first interface that many patients have with an HCT transplant program occurs at the time they come for an initial opinion about the role transplantation may play in the treatment of their disease. Patients may make a consultation appointment to compare a particular program with those of other centers they are considering. These patients meet with a transplant physician to review their options, a financial counselor, and a nurse. The nurse's role is to assist the patient with this decision by explaining the logistics of the program, including the usual length of stay on the inpatient unit and how much of the transplant process will be managed on an outpatient basis. Many patients are interested in the nursing services at the program they are considering and ask questions about the nurse-to-patient ratios. The responsibilities of the patient's caregiver are also reviewed. At that time, many families are concerned with the logistics of relocating and incorporating this intense therapy into their lives. These patients present with a myriad of questions, and the nurse must be versatile in meeting the patients' and families' informational needs in coordination with the transplant team. Nurses often are also responsible for giving information regarding the transplant program to physicians and nurses from the referring center in addition to third-party payers.

Table 30.1 Prework-up/prior to patient's arrival at transplant center

Assessment
Understanding of the overall transplant process and time commitment
Current symptoms from previous therapies or disease
Current coping ability
Current pain
Current blood product requirements
Sedation preference for procedures
Teaching
Length of time for work-up, mobilization, and transplant process
Role of caregiver
Care coordination
Confirm family/friend plan for caregiving
Contact referring physician's office to obtain report
Confirm financial clearance
Confirm housing plan
Carrying out the medical care plan
Maintain working knowledge of proposed transplant plan for patient

Table 30.2 Work-up

Assessment
Patient's current fears and concerns
Barriers to learning
Current pain
Knowledge of disease status
Knowledge of transplant process
Knowledge of patient's rights and responsibilities when participating in medical research
Usual coping strategies
Level of fatigue and usual sleep patterns
Patient's experience in other healthcare environments
Identified caregiver(s)' commitment
Identified caregiver(s)' barriers to learning
Allergies
Current medications and knowledge of purpose
Adherence in taking medications
Culture for presence of antibiotic-resistant organisms
Current central venous access
History of central venous access
Teaching
Logistics for working with home infusion companies and administration of home infusions
Clinic logistics, including how to access care after hours
Importance of having a caregiver during various phases of the transplant process
Purpose of procedures, laboratory tests, and scans required for work-up
Overall transplant process
Usual complications of transplant
Central venous catheter preoperative teaching
Care coordination
Assess ability to adhere to work-up schedule
Confirm financial clearance for transplant
Social work assessment
Nutrition assessment
Carrying out the medical care plan
Maintain working knowledge of proposed transplant plan for patient
Ensure all work-up studies are obtained in a timely manner

Work-up (Table 30.2)

Once a patient has met initial screening and has decided to undergo HCT at a specific center, the nurse's primary responsibility becomes education. The patient must understand the specifics of the rigorous evaluation. The coordination and timing of care during this phase are especially critical if the patient has an unrelated donor. The completion of work-up and the initiation of conditioning must start

Table 30.3 Preconditioning

Assessment
Knowledge of need for compliance during conditioning regimen
Knowledge of side effects to report during conditioning
Caregiver's ability to report symptoms
Caregiver's ability to utilize ambulatory infusion pump if required
History of antiemetics
Assure appropriate patient central venous access
Teaching
Treatment plan and schedule for chemotherapy and total body irradiation
Antiemetic schedule and importance of adherence
Purpose of viral and/or fungal prophylaxis
Purpose of prophylaxis for graft-versus-host disease if appropriate
Care of central venous access
Caregiver education for ambulatory infusion pump if hydration given in ambulatory setting
Importance of laboratory monitoring
Purpose of hydration
Symptoms to report
Differences between previous chemotherapy and conditioning chemotherapy
Importance of compliance with *Pneumocystis* prophylaxis
Care coordination
Research consents
Chemotherapy, total body irradiation and/or radioimmunotherapy order verification with protocol
Dosimetry and simulation appointment with radiation oncology if applicable
Pager/cell phone for patient if conditioning to start in the clinic
Carrying out the medical care plan
Ensure central venous catheter is inserted in timely manner
Ensure antivirals, antifungals, pneumocystis prophylaxis, immunosuppressants, and antiemetic medications are initiated as ordered

on an exact date to allow HSC infusion on the planned date of HSC procurement. The generosity of the volunteer donors must be respected and accommodated.

Preconditioning (Table 30.3)

The nurse plays an important role in the informed consent process, supporting the medical staff's explanations and plans to ensure, as much as possible, that the patient is making an informed decision regarding HCT.

Donor preparation (Table 30.4)

Donors have been called the "forgotten patients" of transplant. The HCT recipient, appropriately, is the center of focus for the transplant team. However, donors also have concerns about their own health and the procedures they will undergo. It is ideal for donors to have a primary nurse with whom they can establish a relationship and who can prepare them for the hematopoietic cell collection and monitor them throughout the procedure. The Foundation for the Accreditation of Cellular Therapy (FACT) has also determined that the donor should be cared for by a different physician than the transplant recipient.

Table 30.4 Donor work-up

Assessment
Current fears and concerns
Barriers to learning
Donor screening per American Association of Blood Banks (AABB) requirements
Knowledge of donation process
Assessment of adequacy of veins for apheresis
Knowledge of patient's rights and responsibilities when participating in medical research
Allergies
Teaching
Donation plan and schedule
Importance of laboratory monitoring
Preoperative teaching if applicable
Symptom management
Care coordination
Assess ability to adhere to work-up schedule
Research consents
Storage of autologous red cells if marrow donation planned
Carrying out the medical care plan
Maintain working knowledge of proposed transplant plan for patient
Ensure all work-up studies are obtained in a timely manner

Table 30.5 Mobilization and collection (autologous patients and allogeneic donors)

Assessment
Knowledge of care of central venous access (if applicable)
Teaching
Purpose of monitoring CBC, CD34$^+$ cells, and electrolytes
Purpose and care of central venous catheter (if applicable)
Specific medications used to mobilize, and usual side effects if applicable
Subcutaneous injections if applicable
Temperature monitoring
Importance of increasing calcium intake
Medications to avoid (e.g. aspirin)
Care coordination
Coordinate home administration of subcutaneous medications
Manage side effect of growth factors
Coordinate stem cell collection and storage with Cellular Therapy Laboratory
Confirm adequate venous access
Carrying out the medical care plan
Administer subcutaneous injections in clinic
Central catheter management
Collect stem cells

Mobilization and collection (autologous patients and allogeneic donors) (Table 30.5)

Nursing care during mobilization must be individualized to the specific medical protocols being utilized in addition to the response of the donor or autologous patient. The nurse must stay in daily contact with the donor or autologous patient during this time as collection schedules can change based on cell yield. The nurse needs to assist in determining whether it is necessary to have a long-term central venous access catheter inserted before mobilization, if a short-term central venous access catheter is sufficient, or if vein-to-vein access may be possible. The donor should be educated regarding monitoring and reporting side effects of administered cytokines and chemokine antagonists (i.e. bone pain, headache and gastrointestinal symptoms) in addition to providing the appropriate interventions for symptom relief [16].

Conditioning (Table 30.6)

Prior to the infusion of stem cells, the patient will receive conditioning therapy to eliminate residual disease (autologous and allogeneic transplants) and prepare the patient's system to accept donor stem cells by creating "space" in the bone marrow and suppressing the patient's immune system (allogeneic transplants) [17]. Conditioning can be chemotherapy (high-dose regimens or reduced-intensity regimens), biotherapy, total body irradiation, radioimmunotherapy, or a combination of these modalities. Chemotherapy used for traditional myeloablative transplants is administered at higher doses than conventional chemotherapy to treat cancer. These high-dose regimens will lead to acute toxicities that may manifest more rapidly and intensely than with standard-dose therapy [18]. The nurse's role is key in safe administration of high-dose therapy and in supporting the patient and caregiver in the management of acute toxicities from the high-dose regimen. Toxicities associated with

Table 30.6 Conditioning

Assessment

Knowledge of potential side effects of conditioning regimen
Response to high-dose chemotherapy, immunotherapy, radioimmunotherapy, and/or total body irradiation
Ability to perform self-care and infection control preventative measures (hand washing, personal hygiene, oral care, etc.)
Renal and fluid status: intake and output; postural vital signs; daily or twice-daily weights; breath sounds, heart sounds; skin turgor; laboratory tests: serum electrolytes, blood urea nitrogen, creatinine
Nutritional status: weight; amount, content, and patterns of nutritional intake
Outpatients:

- Patient/caregiver ability to assess, report, and manage side effects of conditioning regimen
- Knowledge of telephone numbers to access support and emergency care 24 hours per day

Teaching

Treatment plan and schedule, including administration of intravenous hydration, antiemetics, uroprotectants, and other medications
Potential side effects of conditioning regimen (nausea, vomiting, mucositis, diarrhea, fever, etc.)
Prevention and management of side effects
Level of caregiver support required
Guidelines for preventing infection:

- Hand hygiene
- Personal hygiene, oral care, CVC care, etc.
- Nutrition/diet guidelines for immunosuppressed patients
- Avoiding activities with high risk for infection

Outpatients:

- Signs/symptoms requiring inpatient hospitalization
- Access to 24-hour triage and emergency care telephone numbers

Care coordination

Clinic appointment schedules or admission to inpatient unit
Total body irradiation schedule and coordination of care with radiation oncology department
Patient and caregiver education: one-on-one instruction or attendance at caregiver classes

Carrying out the medical care plan

Verification of chemotherapy orders
Administer conditioning therapy, intravenous hydration, and medications (antiemetics, uroprotectants, etc.)
Chemotherapy administration
Drawing and monitoring laboratories
Provide supportive care

CVC, central venous catheter.

high-dose chemotherapy and/or radiation therapy require vigilant monitoring with special emphasis on assessment of fluid, gastrointestinal tract, and renal status. Reduced-intensity regimens will be better tolerated, but will still require expert nursing monitoring to detect toxicities that need to be managed to reduce negative sequelae. Conditioning regimens may be administered in the outpatient or inpatient setting, based upon the type of preparatory regimen chosen, the availability of 24-hour triage and supportive services, and the available level of caregiver support.

Care must be available to outpatients 24 hours per day, 7 days per week in order to provide safely for patients whose conditions may rapidly deteriorate. In general, successful management in the outpatient setting during the conditioning phase of transplant requires a high level of continuous caregiver support. Outpatient teaching places special emphasis on use of ambulatory infusion pumps, patient and caregiver ability to assess, report, and manage the side effects of high-dose therapy, and access to support telephone numbers and 24-hour emergency care. Printed patient and caregiver teaching reference materials containing outpatient guidelines and how to access emergency care are useful tools for the reinforcement of patient and caregiver teaching. Patients and caregivers must understand which symptoms require immediate medical attention (Table 30.7) . Caregivers should also be supported during this physically and emotionally taxing time [19].

Table 30.7 Quick reference for symptoms

Area of concern	Critical emergency DIAL 911	Call clinic now
Alertness, consciousness, activity	• Unconscious • Unable to arouse • Seizure	• New or increased confusion • Change in level of alertness • Mood changes: irritable, tearful, agitated • Sleeplessness • Falling down • Numbness, tingling or loss of movement in limbs • Dizziness • Lethargic • Change in energy level • Tremors/shakiness • Not able to get around • Difficulty swallowing
Bleeding	• Uncontrollable, consistent bleeding • Patient is unconscious	• New or increased bleeding • Bloody urine • New bruising • Unable to stop nosebleed • Bloody diarrhea • Vomiting of blood • 1 or more feminine pad per hour is used • Little red or purple spots on the skin
Blood sugar	• Blood sugar lower than 50 and unable to awaken	• High or low blood sugar • Hard to wake up – use glucagon
Breathing	• Not breathing • Choking – not moving air into chest	• Trouble breathing • Gets "winded" more easily with minimal activity • Feeling as if can't get enough air • Trouble breathing when laying flat • Wheezing with breaths • New or recurrent cough • Persistent continuous cough • Coughing blood or green/yellow material
Central venous catheter (Hickman line)	• Line open to air and patient short of breath • Clamp line immediately	• Line broken or leaking • Face, neck, exit site swelling • Inability to flush • Line fell out • Headache related to infusions • Redness, swelling, or tenderness at exit site • Drainage from exit site
Diarrhea		• Constant or uncontrolled diarrhea • New-onset diarrhea • Diarrhea with fever and abdominal cramping • Whole pills passed in stool • Greater than five times each day • Stool that is bloody, burgundy, or black • Mild abdominal cramping
Fall	• Hit head during fall and • Change in consciousness after fall	• Did not hit head and no changes in consciousness after fall
Fatigue	• Unable to wake up	• Dizziness • Fatigue is getting worse • Too tired to get out of bed or walk to the bathroom • Staying in bed all day
Fever/chills		• Fever greater than 1 degree above usual • Cold symptoms (runny nose, watery eyes, sneezing, coughing) • Shaking chills, temperature may be normal • Temperature greater than 38.3 °C or 100.9 °F by mouth
Mouth pain/ mucositis	• Not breathing	• Having difficulty breathing • Bright red blood in mouth • Pain not controlled by medication • White patches or sores appear on gums or mouth • Difficulty swallowing food or fluid

(*Continued*)

Table 30.7 *(Continued)*

Area of concern	Critical emergency DIAL 911	Call clinic now
Nausea/ vomiting		• Nausea persists without control from antiemetic medications • Projectile vomiting • Uncontrolled, constant nausea and vomiting • Blood or "coffee ground"-appearing material in the vomit • Medicine not kept down because of vomiting • Weakness or dizziness along with nausea/vomiting • Severe stomach pain while vomiting
Pain	• Severe chest/arm pain • Severe squeezing or pressure in chest	• New or uncontrolled pain in body • New headache • Chest discomfort • Pounding heart • Heart "flip-flop" feeling • Painful central line site or area of "tunnel" • Burning in chest or stomach • Pain or burning while urinating • Pain with infusion of medications or fluids into central line
Rash		• Rash with severe pain and or itching • New rash
Swelling		• Sudden swelling with or without pain • Swollen legs, arms and hands
Urination		• Unable to urinate for more than 8 hours • Bloody urine • Pain or burning while urinating

Table 30.8 Bone marrow harvest

Assessment
Results of preharvest donor work-up
Preharvest physical reassessment, as indicated
Verification of informed consent
Understanding of bone marrow harvest process and potential complications
Understanding of signs/symptoms to report to healthcare team postharvest
Ability to access 24-hour triage and emergency care telephone numbers
Teaching
Bone marrow harvest process and procedures:
- Hospital admission location, schedule
- Marrow aspiration sites
- Autologous blood transfusions
- Hospital discharge criteria
- Site care post-bone marrow harvest
- Postharvest iron supplements

Potential complications:
- Pain
- Infection
- Anemia related to blood loss
- Nausea and vomiting (if general anesthesia used)
- Dehydration

Signs/symptoms to report to healthcare team
Access to 24-hour triage and emergency care telephone numbers
For patients receiving unrelated donor marrow:
- Marrow harvested at donor residence (state/country)
- Identity of donor remains unknown
- Marrow arrives via courier
- Anticipated time of unrelated donor marrow arrival

Care coordination
Operating room scheduling
Type and cross-match for autologous stored unit, if stored
Time and location of hospital admission for day surgery
Discharge teaching
Discharge medications
Postharvest outpatient appointment and laboratory draws (generally, complete blood count with differential and platelets)

Bone marrow harvest (Table 30.8)

The technique of harvesting marrow is essentially the same for allogeneic related donors, unrelated donors, and autologous patients. Education will prepare donors or autologous patients for anticipated side effects, outlining those to report to healthcare providers. Nurses educating donors or autologous patients should emphasize the expectations for the marrow harvest, including information about anesthesia and the aspiration procedure, admission to hospital or day-surgery settings, anticipated recovery period and discharge from the hospital or day-surgery to home, pain management plan for marrow aspiration site pain, site care post-harvest, and follow-up visits.

Patients receiving unrelated donor marrow will need instruction regarding when and how the donor marrow will arrive for infusion. Donor marrow is harvested at the medical center closest to the donor's residence, and the marrow is flown to the patient's location accompanied by an Unrelated Donor Program courier. Patients will also be told that the identity of their unrelated donor must remain unknown for a period of time to protect the donor.

Autologous patients will have their marrow harvested and cryopreserved (frozen) for later use. The bone marrow will be thawed and infused after they receive conditioning therapy.

Transplant phase (Table 30.9)

The stem-cell product infusion is very similar to a blood transfusion. The rate of infusion, method of administration, and potential side effects depend on whether the product is cryopreserved or not. Dimethyl sulfoxide (DMSO) is generally used as the preservative for cryopreserved marrow, peripheral blood stem cells, and umbilical cord blood. Infusion of products cryopreserved with DMSO tends to cause a significant number of transient, self-limited side effects amenable to premedication [14,15,20]. These side effects are rarely severe (less than 1% of all complications), although life-threatening complications have been reported [21]. Side effects to be expected with cryopreserved cells are nausea/vomiting, tickle in the throat, facial flushing, hypertension or hypotension, bradycardia or tachycardia (can be delayed), cardiac dysrhythmia, chest tightness, cough, flushing, chills, fever, abdominal cramping, diarrhea, headache, transient taste and smell of DMSO (oyster, garlic, or creamed corn odor), and/or the appearance of red urine post-infusion. Complications from infusion of non-cryopreserved products may include volume overload and pulmonary abnormalities from fat or cellular debris emboli. In addition, patients may experience symptoms similar to blood transfusion reactions (chills, urticaria, fever, etc.) or hemolysis related to ABO incompatibility.

Patients and caregivers benefit from nursing education about the infusion procedure, potential side effects, and premedications. Important care coordination considerations for nurses include ensuring initiation of GVHD prophylaxis at the appropriate time for allogeneic patients and timing stem-cell product prehydration and premedications with the arrival of the products on the unit or the patient care area.

Pre-engraftment (Table 30.10)

The majority of complications that occur prior to engraftment are the result of toxicities associated with the high-dose conditioning regimen and/or the administration of immunosuppressive medications. Nursing care is directed at strategies to prevent potential

Table 30.9 Transplant

Assessment

Preinfusion:
- Knowledge of stem-cell infusion process
- Renal and fluid status: intake and output; postural vital signs; weight; breath sounds; skin turgor; laboratory tests: serum electrolytes, blood urea nitrogen, creatinine
- Response to prior red blood cell transfusions
- Adequacy of venous access for infusion of stem cells (central venous access required for infusion of cryopreserved stem-cell products due to DMSO; central venous access preferred for non-cryopreserved products)
- Availability of emergency medications

During infusion:
- Frequent vital sign monitoring and assessment to detect the early onset of potential infusion-related complications

Postinfusion:
- Frequent vital sign monitoring and assessment to detect postinfusion-related complications
- Tolerance of cell infusion
- Renal function and fluid status: intake and output (general goal is to maintain urine output at 2–3 mL/kg/h); presence of hematuria due to red-cell lysis

Teaching

Location for stem-cell infusion (inpatient versus outpatient setting)
Anticipated timing of stem-cell product arrival on unit or in outpatient department
Schedule for stem-cell infusion, including multiple days if necessary
Stem-cell infusion procedure:

Cryopreserved
- Prehydration
- Premedications (e.g. antiemetics, diphenhydramine, hydrocortisone, acetaminophen)
- Transport of cryopreserved cells
- Thawing of cells at bedside
- Infusion of cells via central venous catheter

Non-cryopreserved
- Premedication (if patient previously experienced transfusion reactions to red blood cell transfusions)
- Transport of cells to patient care area
- Infusion (generally via CVC)

Potential complications:

Cryopreserved
- Reactions to cryoprotectant DMSO including nausea/vomiting, tickle in throat, facial flushing, hypertension, hypotension, bradycardia, tachycardia, cardiac arrhythmia, chest tightness, cough, flushing, chills, fever, abdominal cramping, diarrhea, headache, transient taste and smell of DMSO, appearance of red urine postinfusion
- Prevention/treatment of throat tickle and nausea secondary to DMSO by antiemetics, sucking on hard candy, eating or smelling an orange
- Transfusion reactions (if allogeneic)
- Volume overload
- Allergic reaction
- Pulmonary microembolism (clumps of cell debris may occur after thawing): shortness of breath, dyspnea, cough

Non-cryopreserved
- Fluid overload
- Pulmonary microembolism secondary to fat emboli (may occur with infusions of bone marrow): shortness of breath, dyspnea, cough
- Transfusion reactions (if allogeneic)
- Allergic reactions
- Excessive anticoagulation: may occur with rapid or large-volume infusions (marrow and blood cells anticoagulated with heparin and/or citrate solutions)

Care coordination

Initiation of graft-versus-host disease prophylaxis pre-transplant
Coordinate arrival of stem-cell product with department or service handling and/or processing cells:
- Apheresis unit (related allogeneic peripheral blood cells)
- Cryopreservation laboratory [cryopreserved cell products (bone marrow, umbilical cord blood, peripheral blood cells)]
- Operating room (related allogeneic bone marrow)
- Unrelated donor program (unrelated donor peripheral blood cells or bone marrow)

Carrying out the medical care plan

Administer prehydration and premedications appropriately timed with arrival of stem-cell product
Administer stem-cell product and monitor for complications

DMSO, dimethyl sulfoxide.

complications, and also early detection and prompt implementation of appropriate interventions if complications develop. Systematic and astute assessment skills are required to identify subtle clues indicative of multiple potential complications [1]. For the pancytopenic patient, transplant nurses play a critical role in assisting the patient in preventing infections and bleeding complications and in managing fatigue. Nurses are also critical to help the patient manage pain from mucositis and to monitor fluid, electrolyte, and nutritional status.

Coordination of care can be very complex during this phase. Neutropenia and thrombocytopenia are perhaps the most dangerous complications during the pre-engraftment period. Nurses should follow evidence-based guidelines for the care of the neutropenic patient [22–24]. Patients who are outpatients during all or part of the pre-engraftment phase require frequent, often daily, clinic visits, with intense patient education to ensure that they can manage the complications and report promptly symptoms requiring care. Patients often require administration of multiple red blood cell and platelet transfusions, intravenous fluids and parenteral nutrition, and multiple intravenous medications. Whether in the inpatient or ambulatory clinic setting, infusing all required intravenous medications and fluids presents a major challenge. Many transplant centers place double-lumen central venous catheters for use throughout the transplant. Patients may require additional intravenous access during the pre-engraftment phase in order to administer all of the required intravenous medications and fluids. Additionally, patients usually require frequent collections of blood specimens, diagnostic procedures, examinations, or appointments with various members of the healthcare team, coupled with ongoing needs for education, completing activities of daily living, and psychosocial support.

Table 30.10 Pre-engraftment

Assessment

Assessments for potential conditioning-related toxicities:

- **Mucositis:** color/integrity of oral mucosa; volume and consistency of oral mucus; airway patency; general level of consciousness; subjective complaints of pain and/or difficulty swallowing; ability to perform oral care and maintain fluid/nutritional needs
- **Nausea/vomiting:** subjective reports of nausea; frequency and appearance of emesis, including gastroccult for presence of blood; abdominal assessment; fluid status, including intake and output, postural vital signs; effectiveness of antiemetic therapy
- **Diarrhea:** amount, frequency, appearance of stool, presence of blood; abdominal assessment; fluid status, including intake and output; subjective complaints of fullness, cramping, pain, microbiology culture reports, effectiveness of antidiarrheal therapy
- **Infection:** fever and/or chills unrelated to blood products or other medications; skin integrity, including oral and perineal areas; presence of adventitious breath sounds or cough; subjective reports of pain, weakness, fatigue; microbiology culture reports; hematologic laboratory values; chest X-ray report
- **Bleeding:** appearance and integrity of skin, sclera, mucous membranes; appearance of oral secretions; presence of frank or occult blood in urine, stool and emesis; mentation and level of consciousness, vital signs noting hypotension or tachycardia; laboratory values (hematocrit, platelet count, coagulation studies, hepatic and renal function tests)
- **Sinusoidal obstructive syndrome:** weight gain; increased abdominal girth; abdominal distention; right upper quadrant pain; hepatomegaly; mentation and level of consciousness; jaundice (skin and/or sclera); laboratory values (liver function tests including serum bilirubin, SGOT, alkaline phosphatase)
- **Pain:** onset, location, description, intensity (using rating scale), aggravating and relieving factors; effectiveness of interventions; psychosocial assessment; effect of pain on activities of daily living
- **Renal insufficiency:** strict intake and output; daily or twice-daily weight; postural blood pressure and heart rate; pulmonary assessment including respiratory rate, quality and presence of adventitious breath sounds; cardiac assessment, neck vein distention; presence of edema or ascites; administration of nephrotoxic drugs; laboratory values (serum blood urea nitrogen, creatinine, electrolytes; urine specific gravity)
- **Pulmonary:** respiratory rate, rhythm, depth, quality; breath sounds; existence and quality of cough; sputum production; mentation and level of consciousness; presence of cyanosis or skin mottling; subjective complaints of shortness of breath, dyspnea, or pain; oxygen saturation

Knowledge of patient/caregiver of potential complications

Ability to participate in self-care measures to treat and/or prevent complications

Ability of caregiver to participate in patient support

Teaching

Recognition, reporting and management of post-transplant complications:

- Mucositis
- Nausea/vomiting
- Diarrhea
- Infection
- Bleeding
- Sinusoidal obstructive syndrome
- Pain
- Renal insufficiency
- Pulmonary complications

Reinforcement of guidelines for preventing infections:

- Hand hygiene
- CVC care
- Personal hygiene, oral care, etc
- Nutrition/diet guidelines for immunosuppressed patients
- Avoiding activities with high risk for infection

Reinforcement of guidelines for preventing bleeding episodes:

- Careful oral hygiene with a soft-bristled toothbrush
- No rectal maneuvers
- Avoid medications that increase risk of bleeding
- Avoid falls
- Use electric razors for shaving
- Avoid nose blowing or picking
- Women with menses should use pads, not tampons

Rationale and procedures for administration of blood products, parenteral fluids and nutrition, medications

Anticipated time to engraftment

Signs and symptoms of engraftment

Care coordination

Coordinate multiple healthcare provider appointments (outpatient) or healthcare provider examinations and tests (inpatient)

Provide patient and caregiver education: one-on-one instruction or attendance at caregiver classes, for new caregivers

Carrying out the medical care plan

Blood product administration:

- Platelet transfusions (often daily or multiple times per day)
- Packed red blood cell transfusions

Intravenous fluids:

- Total parenteral nutrition/lipids
- Hydration

Medication administration:

- Graft-versus-host disease prophylaxis (allogeneic patients)
- Antibiotics, antivirals, antifungals
- Antiemetics
- Opioid/non-opioid analgesia (patient-controlled analgesia in inpatient setting)
- Investigational drugs

Multiple laboratory draws

Frequent physical assessments and vital signs (inpatient, every 4 hours and as needed; outpatient, every clinic visit and as needed)

Physical care:

- Bath and skin care
- Oral care
- CVC dressing changes
- Exercise/ambulation

CVC, central venous catheter; SGOT, serum glutamic-oxaloacetic transaminase.

Early post-engraftment (Table 30.11)

Engraftment typically occurs between days 14 and 28 post-transplant, depending on the stem-cell source. The most common issue in the early post-engraftment period for allogeneic transplant patients is acute GVHD. Nurses play an important role in assessing patients for this condition and in teaching patients and caregivers how to monitor for its signs and symptoms. Transplant nurses must have a thorough understanding of the pathophysiology, clinical manifestations, and management of GVHD [25].

The nurse plays a key role in preparing the patient and family for discharge from the hospital. Criteria for transition from inpatient to outpatient settings will differ based on institutional policies, the patient's condition, the availability of skilled outpatient teams, and family caregiver support. Caregivers must be knowledgeable in recognizing, managing, and appropriately reporting complications, and be competent in performing aspects of the patient's care. Detailed and structured discharge teaching is necessary to ensure adequate understanding of critical information by patients and caregivers [26].

Hospital readmissions after initial hospital discharge to the ambulatory care setting frequently occur during the early post-engraftment phase [7]. Coordination and communication of patient care issues between the nursing staff of the inpatient unit and the ambulatory care setting allow for smooth transition and continuity of care. Particular attention needs to be given to caregivers' ability to cope continuously with their multiple demands and roles.

Table 30.11 Early post-engraftment

Assessment

Ongoing assessment for conditioning-related toxicities (see Table 30.10)

Signs and symptoms of GVHD:

- **Skin**: itching; redness or maculopapular rash on palms of hands, soles of feet, ears, trunk, extremities; erythroderma
- **Liver**: right upper quadrant pain; hepatomegaly; jaundice; laboratory values (elevated serum bilirubin, SGOT, alkaline phosphatase)
- **Gut**: nausea; vomiting; anorexia; diarrhea; abdominal cramping and pain

Readiness for discharge from hospital:

- Availability of caregiver on discharge
- Competency of patient and caregiver to: (1) recognize, report, and manage post-transplant complications; (2) manage outpatient schedules and treatments; and (3) administer outpatient IV fluids and medications
- Knowledge of telephone numbers to access emergency care and support 24 hours per day on discharge

Caregiver ability to provide support

Teaching

Signs and symptoms of acute GVHD

Rationale and procedures for diagnostic testing for GVHD if signs and symptoms develop (e.g. skin biopsy, liver biopsy, and/or endoscopy)

Management of GVHD (adding immunosuppressive medications to current GVHD prophylaxis), dietary restrictions

Hospital discharge planning:

- Criteria for discharge from inpatient to outpatient setting (e.g. nausea/vomiting/pain controlled; blood counts supportable; number and type of IV infusions or medications)
- Level of caregiver support required on discharge (generally constant support required post-hospital discharge)
- Outpatient administration of IV fluids and medications
- Discharge medication schedule: immunosuppressant medications for GVHD prophylaxis and/or treatment (allogeneic patients), prophylaxis for *Pneumocystis carinii* pneumonia, antivirals, antibacterials, antifungals, electrolyte replacements, antiemetics, etc.
- Importance of reporting inability to take medications prescribed
- Outpatient appointment schedules on discharge

Recognition and management of post-transplant complications

Likelihood of readmission to hospital post-initial discharge

Care coordination

Coordinating multiple healthcare provider appointments (outpatient) or healthcare provider examinations and tests (inpatient)

Scheduling procedures (marrow aspirations, chest-X-rays, etc.)

Transitioning care from inpatient to outpatient setting

Carrying out the medical care plan

Blood product administration:

- Platelet transfusions (often daily or multiple times per day)
- Red blood cell or whole blood transfusions

Intravenous fluids:

- Total parenteral nutrition/lipids
- Hydration fluids
- Patient-controlled analgesia (inpatients)

Medication administration:

- GVHD prophylaxis
- Antibiotics, antivirals, antifungals
- Opioid/non-opioid analgesics
- Electrolyte replacements
- Investigational drugs
- Antiemetics

Multiple laboratory draws

Frequent physical assessments and vital signs (inpatient, every 4 hours and as needed; outpatient, at each clinic visit and as needed)

Physical care:

- Bath and skin care
- Oral care
- CVC dressing changes
- Exercise/ambulation

CVC, central venous catheter; GVHD, graft-versus-host disease; IV, intravenous; SGOT, serum glutamic-oxaloacetic transaminase.

Intensive care management of the transplant patient

Most transplant patients require complex, high-acuity levels of care throughout their inpatient stay [27]. Additionally, it is estimated that up to 40% of patients undergoing HCT will require nursing skills typical of most ICUs, including hemodynamic monitoring, non-invasive cardiac monitoring, administration of inotropic and vasoactive medications to support blood pressure, and mechanical ventilatory support [28]. The need for ICU support will vary based on the type of HCT performed and how ill the patient is prior to transplant. All transplant nurses, whether ICU trained or not, need to be aware of early signs and symptoms of common complications of transplant so as to intervene early and prevent morbidity and mortality [27,28].

Management of critically ill transplant patients combines the complexity of oncology and critical care nursing skills, presenting significant challenges to the provision of expert nursing care. Oncology nurses generally are not trained or skilled in the management of critically ill patients. Conversely, critical care nurses generally do not have an oncology background. Patients with critical care complications may be transferred to a critical care unit. However, many institutions have worked towards merging the two specialties of oncology nursing and critical care nursing to meet the needs of these patients by training transplant nurses to provide intensive care on the transplant unit or by cross-training ICU staff to specialized transplant procedures [29]. Challenges to each approach include the maintenance of nurses' competency. Transplant nurses may find it difficult to keep critical care skills up-to-date if the volume of transplant patients requiring critical care is low. Critical care nurses may face similar issues in maintaining transplant competencies and skills. Each institution must evaluate the available resources, outcomes of care, and cost-effectiveness of cross-training staff and maintaining clinical competencies when determining models for providing critical care to transplant patients [30,31].

Substantial progress has been made in treating the complications of HCT. Past reports of close to 100% mortality rates in HCT patients requiring ICU care are no longer the reality; the current mortality rate in ICUs is less than 50% [32–36]. Mortality remains highest for those HCT patients admitted to ICU for sepsis or respiratory failure [32,33].

Relapse post-transplant

Some patients may fail to respond to the HCT or, after initial response, relapse of underlying disease may occur [37]. For patients with disease relapse, options for care may include standard or experimental chemotherapy, donor lymphocyte infusion or other cellular therapies, discontinuation of immunosuppressive therapy, a second HCT, or palliative care [37] (see Chapter 71). Nurses play a significant role in clarifying the treatment options presented by the medical staff. Nurses also serve as advocates for the patient and family, helping to communicate the patient's individual goals clearly to the health-care team.

Discharge (Table 30.12)

Preparation for long-term recovery begins during the treatment phase and is part of the ongoing nursing care process. Discharge education is provided by nurses to review symptoms of possible late effects of transplantation, such as chronic GVHD and infectious risks, and make recommendations related to activities of daily living for the first year after HCT (Table 30.13). It is also a good opportunity to discuss possible cognitive, sexual, and emotional concerns. Some large centers accomplish this educational goal through individual classes. This effort facilitates the hand-over of care from the transplant center to the care of the referring physician.

Table 30.12 Discharge from transplant program

Assessment
Knowledge of infectious risks
Knowledge of expected follow-up office visits and laboratory testing
Nutritional needs
Need for continuance or removal of CVC
Allogeneic patients: • Current symptoms of GVHD • Visual examination of skin • Skin biopsy • Schirmer's test • Knowledge of chronic GVHD
Teaching
Symptoms of chronic GVHD
Recovery of immunity
Recommendations for minimizing daily infectious risks (see Table 30.13)
Recommendations for returning to work or school
Management of fatigue
Management of possible problems related to sexual function
Management of cognitive and emotional issues
When to report fever
Necessity for consistent medical follow-up for life
Care coordination
Medication list
Nursing care plan for local nursing care provider
Home healthcare agency if needed
Special transfusion requirements and preparation of products (irradiation and CMV screening if CMV negative)
Interface with health insurance carriers as needed
Assist with research coordination
Time after transplant

CMV, cytomegalovirus; CVC, central venous catheter; GVHD, graft-versus-host disease.

Patients often express feelings of anxiety when leaving the security of the transplant program that they have relied on so heavily. If the patient is being discharged from the transplant center to their referring physician, identifying a designated contact person or group at the transplant center for both the patient and the referring physician for consultation on transplant-related problems is essential. This contact person can decrease the anxiety of the patient and caregiver and provide the referring physician access to transplant expertise and continuity of the medical plan. General guidelines should be provided by the transplant center for the referring physician that details the important aspects of long-term care of the transplant recipient [38].

Long-term recovery (Table 30.14)

Nurses, under the guidance of the transplant center medical team, can successfully act as liaison between the referring physician and the transplant physicians. They can collect important and pertinent information necessary to triage transplant-related problems and, after discussion with the transplant physicians, relay possible solutions to the team providing care at home. One organized approach is to conduct long-term follow-up rounds on a regular basis to discuss non-urgent problems. Issues most frequently requiring the expertise of the transplant team are the diagnosis and treatment of chronic GVHD, pulmonary complications, gastrointestinal symptoms, engraftment issues, treatment of serious and life-threatening infections, booster immunization, recurrent disease, and the development of secondary malignancies [39].

Table 30.13 Common questions asked by hematopoietic stem-cell transplantation (HSCT) and long-term follow-up (LTFU) patients utilized at the Fred Hutchinson Cancer Research Center

Questions often asked	**Time after transplant**			
The general guidelines below may not apply to your case. You must discuss with your physician to assess if these rules apply to you.	**All patients Less than 6 months**	*Not* **receiving immunosuppression 6 months to 1 year**	**Receiving immunosuppression 6 months to 1 year**	**Receiving immunosuppression More than 1 year**
School	No	No	No	OK
Hot tubs (1)	No	OK (1)	No	No
Swimming (1) (avoid head submersion and diving, use sun-screen)	No	OK (1)	No	OK
Gardening (digging in soil); mowing the lawn; raking leaves	No	No	No	No
Having plants in the home (not handling)	OK	OK	OK	OK
Making/kneading yeast breads	No	OK	OK	OK
Carpenter work	No	No	No	No
Occasional woodworking (sawdust)	No	OK	OK	OK
Animals, birds, reptiles, fish, other (not handling feces, litter boxes, cleaning utensils, cages/tanks, etc.):				
• New pets in patient's household	No	No	No	No
• Cats/dogs (not sleeping with pets)	OK	OK	OK	OK
• Domestic birds (parakeets, parrots, etc.) (not with respiratory problems)	No	OK	OK	OK
• Poultry and wild birds (pigeons, chickens, ducks, geese, other wild birds)	No	No	No	No
• Small cage rodents (gerbils, rabbits, hamsters, guinea pigs, hedgehogs, prairie dogs, etc.) (do not handle)	No	OK	OK	OK
• Reptiles (snakes, turtles, lizards, iguanas, etc.); ferrets	No	No	No	No
• Farm animals (pigs, horses, cows, llamas, etc.) (do not handle; stay out of barns full of hay)	No	OK	OK	OK
• Wild and game animals (deer, elk, squirrels, bears, etc.); exotic animals (monkeys, etc.) (do not handle)	No	No	No	No
• Zoos and petting zoos	No	No	No	No
• Public aquariums (do not touch marine life in handling tanks) (3)	OK (3)	OK (3)	OK (3)	OK (3)
• Animal trophy mounts in the house	OK	OK	OK	OK
• Fishing (fresh and salt water) (OK to handle fish if wearing gloves; do not bait hooks)	OK	OK	OK	OK
• Horseback riding (stay out of barns full of hay)	No	OK	OK	OK
• Hunting – patients without CVC (wild game and birds) and sport shooting (2) (wear disposable medical gloves when handling game; do not clean game)	No	OK (2)	OK (2)	OK (2)
• Golfing (2) (sun protection required; without venous catheter device)	No	OK	OK	OK
• Spectator events and crowds (3) (church, movies, games, etc.) (no hand shaking)	No (2)	OK (3)	OK (3)	OK (3)
• Sexual activity	OK	OK	OK	OK
• Working with mechanical equipment (oil changes, working on cars and engines, etc.)	OK	OK	OK	OK
• Camping and hiking	OK	OK	OK	OK
• Down comforters (with cover)	OK	OK	OK	OK

CVC, central venous catheter.

(1) *NO* swimming if venous access device still in place (i.e. catheter). No patient history of sinusitis. Chlorinated and well-maintained pools preferable over uncertain water conditions of lakes, rivers, and sea for swimming, Do not recommend swimming in pools used by non-toilet-trained babies and children. Water aerobics OK.

(2) Shooting of rifles and shotguns and golfing are not recommended if venous access device still in place (i.e. catheter).

(3) Recommend caution and an understanding of the risks involved when participating in public events or going to locations with large crowds.

(4) Real Christmas trees: in the water reservoir of the tree stand, use a solution of 1 part chlorine solution (Clorox) in 10 parts water.

Other reminders:

Minimize: **exposure to dirt and aerosolized material**.

Minimize: **sun exposure and use of sun-screen (SPF >15%)**.

Use: **hat, long-sleeve shirts** and **pants** if outside for long periods of time.

Avoid contact with people with **respiratory illness** or other **transmissible diseases**.

The need for the transplant team to act as a resource may persist for a few months to several years. While patients who live at a distance from the transplant center benefit from periodic follow-up visits to the transplant center, the general oncologist or hematologist at home can provide the routine follow-up care. Timely and consistent communication between the transplant centers and community practices is essential for safe continuity of care [40]. Transplant nurses can also provide ongoing support in the outlying communities by offering educational programs and by sending out educational material when the need is recognized. Facilitation of support groups is another way for transplant nurses to provide ongoing education and support for local patients in the long-term recovery phase.

If the transplant center is involved in ongoing research, the research nurse plays an integral role in continuing data collection and adherence to research protocols. In some research centers, patient health questionnaires are regularly mailed to post-transplant patients to update demographics, quality-of-life information and survival documentation. Research nurses can triage problem issues that are identified from the questionnaires.

The role of the nurses working with the HCT patients during long-term recovery requires patience and perseverance when considering the recurring nature of chronic GVHD and other long-term issues. As in other phases of HCT nursing, the work is rewarding and challenging, and it allows for the establishment of long-term and trusting relationships. While nurses working in the office setting may find the problems of this population to be daunting at times, the eventual recovery and return of many patients to a satisfying and full life is a reward experienced by those who are fortunate enough to work with these patients.

Table 30.14 Long-term recovery

Assessment
Fatigue
Pain
Functional status
Complete blood count
Kidney function
Liver function
Magnesium level
Drug levels
Chronic GVHD symptoms (allogeneic patients):

- **Skin**: erythema, dryness, macular or urticarial rash and pruritis, hyperpigmentation, vitiligo, mottling, lichenoid plaques, hyperkeratosis, exfoliation scleroderma or morphea
- **Mouth**: dryness, mucositis, erythema, ulcerations, lichenoid changes, striae, tightness around the mouth, sensitivity to hot, cold, or spicy foods, gingivitis
- **Eyes**: dryness, grittiness, blurring, excessive tearing, photophobia, and pain
- **Liver**: elevated liver function tests not attributable to other causes and sometimes jaundice
- **Gastrointestinal system**: anorexia, nausea, vomiting, diarrhea, dysphagia, malabsorption, weight loss, early satiety
- **Lungs**: cough, wheezing, dyspnea on exertion, history of recurrent bronchiolitis or sinusitis, bronchiolitis obliterans
- **Nails**: ridging, onychodystrophy, onycholysis
- **Hair**: premature graying of scalp hair, eyelashes, eyebrows, thinning of scalp hair, alopecia, decreased body hair
- **Vagina**: dryness, dyspareunia, stricture or stenosis, erythema, atrophy or lichenoid changes not induced by ovarian failure or other causes
- **Myofascia**: stiffness and tightness with restriction of movement, sometimes with swelling, pain, cramping, erythema, and induration, most commonly affecting the forearms, wrists and hands, ankles, legs, and feet, contractures
- **Muscles**: proximal muscle weakness, cramping
- **Skeletal**: arthralgia of large proximal girdle joints and sometimes smaller joints
- **Serosal**: unexplained effusions involving the pleural, pericardial or peritoneal cavities
- **Laboratory:** Thrombocytopenia, eosinophilia, hypogammaglobulinemia
- **Energy level**: unusual fatigue

Medication adherence
Nutritional needs
Symptoms of infection
Hormonal issues
Neurological/cognitive symptoms
Sexual dysfunction

Teaching
Symptoms to be reported: skin changes, nausea, anorexia, weight loss, diarrhea, dysphagia, dry or sensitive mouth, dry, gritty eyes or excessive tearing, coughing, wheezing, or shortness of breath, thinning of scalp hair, ridged nails, loss of range of motion or stiffness, vaginal symptoms
When to report fever
How to access medical help after hours
Review of infection prevention
Importance of medication adherence
Importance of reporting abnormal lesions or lumps, bowel changes, or abnormal vaginal bleeding
Importance of regular exercise

Care coordination
Healthcare provider appointments
Medication administration
Laboratory draws
Return visit to transplant center at 1-year anniversary of transplant and thereafter as needed
Vaccination schedule post-transplant
Allogeneic patients:

- Plans for work-up of chronic GVHD symptoms based on assessment
- Plans for treatment of chronic GVHD

GVHD, graft-versus-host disease.

Nursing practice issues in hematopoietic stem-cell transplant

Various nursing roles are needed to successfully care for transplant patients. The organization of nursing roles usually parallels that of the center in which the program resides and is based on that institution's nursing philosophy and care delivery model. In the ambulatory setting, nursing models must complement the medical model for successful care delivery. For example, primary care in the outpatient setting is often structured by having a specific registered nurse work with a specific provider caring for one group or team of patients. Table 30.15 gives descriptions of the various nursing roles.

Achieving and maintaining an expert nursing staff is a constant challenge for institutions with HCT programs. Initial orientation of a nurse with oncology experience generally takes 6–8 weeks. After this time, the nurse can be counted in staffing patterns but is not considered fully competent until they have completed their first year. The nurse-to-patient ratio is also an issue that must be considered when planning an HCT unit. Most inpatient units staff on a ratio of one nurse to two or three patients. This is usually a much lower ratio than on other oncology units and may need to be justified to hospital administrators. Patients develop strong feelings of trust and confidence in specific nurses, and facilitating work schedules to maximize these relationships can be a challenge for nurse managers.

Continuing education must be built into HCT nurses' work schedules. This education includes updates and refreshers on nurse practice topics and also education on new medical protocols. It is also important for the nurses to remain up-to-date with the results of medical research. Each unit should identify topics of high risk and high complexity that qualify for annual competency review and testing. Examples on an inpatient unit include "Administration of high-dose chemotherapy" and "Administration of stem cells." Examples in an outpatient clinic include "Steroid-induced diabetes teaching" and "Donor screening." These nurses are at high risk for experiencing job-related stress, moral distress, and compassion fatigue as they work in fast-paced units with acutely ill patients with uncertain outcomes [41]. Flexible scheduling

Table 30.15 Nursing role descriptions in hematopoietic stem cell transplantation

Nursing title	Role description
Inpatient staff RN	Cares for patients requiring acute care. Includes assessment, patient teaching, and carrying out the medical care plan. Inpatient nurses may care for patients on a designated transplant unit or on an oncology unit
ICU RN	Cares for patients requiring critical care. Includes assessment, patient teaching, and carrying out the medical care plan. ICU nurses may care for patients in an ICU incorporated into the transplant unit or in a main hospital ICU
Nurse coordinator	Coordinates pre-transplant preparations including donor identification. Initiates patient education regarding transplant process. May continue as case manager during patients' transplant course. This position is required of National Marrow Donor Program designated centers
Discharge planning RN	Assists team in planning and coordinating patients' discharge from hospital to ambulatory setting. Provides patient and caregiver education required to manage care at home
Outpatient clinic RN	Cares for patients requiring ambulatory care. Includes assessment, triage, care coordination, patient teaching, and carrying out the medical care plan
Outpatient infusion RN	Cares for patients receiving infusions and transfusions. In many centers the stem cell infusion occurs in the outpatient infusion unit
Home infusion RN	Cares for the patients receiving infusions in the home setting. Educates patients and caregivers to administer intravenous solutions in the home
Apheresis RN	Cares for patients and donors undergoing apheresis procedures
Long-term follow-up RN	Cares for patients after the acute phase of transplant. Provides education and triage for ongoing complications or late effects of transplant
Research RN	Partner with the principal investigator to implement research protocols. Coordinates research activities with primary care team
Nurse manager	Responsible for nursing care delivered in a specific unit or clinic. Ensures appropriate staffing levels for the safe delivery of care
Clinical nurse specialist	Responsible for advancing transplant nursing practice by promoting evidence-based practice, conducting nursing research, creating nursing care guidelines, and evaluating outcomes of nursing care at the population level
Nurse educator	Responsible for orientation and continuing nursing education for transplant nurses
ACP (Advanced Care Provider)	Provides medical care under the direction of the attending physician. Performs procedures such as lumbar punctures and bone marrow biopsies

ICU, intensive care unit; RN, registered nurse.

and supporting time-off requests assist many nurses to keep their resilience to continue to work with these patients. It is also important that the nurses have time to share their experiences with each other and members of the healthcare team as they may not be understood by other support people in their lives, such as family members or even other healthcare professionals. It is important for HCT nursing leaders to have a proactive strategy to prevent "burnout" in their staff. The emotional labor of caring and compassion fatigue can be alleviated by creating a community of caring at work, professional boundaries, and enriched personal life [42].

The need for HCT nurses to network on a national level has been identified since the 1980s, when many transplant units were established. Nurses in the initial transplant centers organized national conferences, including conferences in Seattle, Minneapolis, and Omaha. The conferences were very well attended but a stress on the resources of the individual centers. In 1989, the Oncology Nursing Society acknowledged the unique needs of several subspecialties in oncology nursing, and created "Special Interest Groups" (SIGs). The Blood and Marrow Stem Cell Transplant (BMSCT) SIG of the Oncology Nursing Society (ONS) was one of the initial 10 SIGs and remains one of their largest.

HCT nursing requires unique expertise, and efforts have been made to delineate standards of nursing care. The ONS has created the "Fundamentals of Blood and Marrow Transplant Webcourse," which covers basic information for nurses entering the field of HCT. The ONS has announced a new certification in HCT nursing for experienced nurses, The first Blood and Marrow Transplantation Certified Nurse (BMTCN™) Examination was offered in February 2014. Nurses who are successful in passing the test will earn the credential "BMTCN" [43,44].

In 1998, the Center for International Bone Marrow Transplant Research/American Society for Blood and Marrow Transplantation (CIBMTR/ASBMT) agreed to have a concurrent nursing conference with their "Tandem" annual medical conference coordinated by the ONS BMSCT SIG. This nursing conference has been presented for over a decade, and has grown from a half day to three full days. In 2008, the ASBMT Board of Directors identified a need for nursing input in their initiatives, and requested that Registered Nurse members establish a SIG within the Society. This group was initiated in 2009. Nursing SIG members sit on several subcommittees of the ASBMT and also co-Chair the annual nursing conference with leaders from the ONS BMSCT SIG.

Conclusion

Expert nursing care is essential to the success of an HCT program. In most HCT programs there is teamwork, respect, and mutual appreciation among the multidisciplinary staff. Dr. E. Donnall Thomas, founding Medical Director of the Fred Hutchinson Cancer Research Center's Transplant Program and joint recipient of the 1990 Nobel Prize in Physiology or Medicine, called transplant nurses "his secret weapons" [45]. Nurses who are drawn to this subspecialty within oncology are rewarded by intense, intimate, and long-term relationships with the patients and their families. There is great satisfaction in knowing that they have made a positive difference in the lives of these patients.

CHAPTER 31

Ethical Issues in Hematopoietic Cell Transplantation

David S. Snyder
City of Hope Medical Center, Duarte, CA, USA

Introduction

Many of the ethical issues raised in hematopoietic cell transplantation (HCT) are common to those involved in other forms of medical therapy utilizing advanced technologies. These issues are informed by the traditional principles of patient autonomy and the importance of informed consent and confidentiality; justice, that is, the fair allocation of limited resources; beneficence and non-maleficence; and fidelity or non-abandonment when the goals of treatment shift from cure to supportive care.

However, certain unique features of HCT compound the complexity of these ethical issues, including: the young age of most patients; the fact that most of the diseases are life threatening and often fatal within a short time in the absence of an HCT, yet are potentially curable with this treatment; the fact that a living donor is required who is often a minor; the ability to select potential donors for an affected sibling by utilizing preimplantation genetic diagnosis; the great financial expense of the procedure and controversies about reimbursement; and the fact that survivors of HCT may be cured of their primary malignant disease but may face other serious complications, such as sterility, chronic graft-versus-host disease (GVHD), second malignancies, psychologic distress, sexual dysfunction, cognitive impairments, and occupational disability. In this chapter, some of the ethical issues in HCT are reviewed under the following general headings: who is eligible for HCT, informed consent for the patient, informed consent for the donor, alternative sources of stem cells, HCT for non-malignant diseases, and end-of-life issues.

Who is eligible for HCT?

Case scenario 1

A 49-year-old man with Stage II multiple myeloma has a human leukocyte antigen (HLA)-identical sibling. He is eligible for a protocol utilizing tandem autologous HCT followed by a reduced-intensity regimen allogeneic HCT. His physicians feel that this approach represents his best chance for long-term, disease-free survival and possible cure of his myeloma. His insurance plan considers this treatment plan experimental, and will only authorize a single autologous HCT.

Case scenario 2

A 32-year-old man with advanced chronic myelogenous leukemia (CML) has no sibling donors available for allogeneic HCT. Although his company's insurance plan covers the costs of procurement and the actual transplant for a matched unrelated donor HCT, it will not pay for the search costs, which the patient cannot afford. Although the company sponsors a donor drive in the name of this patient, he cannot access any of the donors who might be identified.

These two scenarios, which are based on actual cases, help to highlight some of the difficult issues involved in determining who undergoes an HCT procedure. This process involves both medical decision-making based on clinical and protocol-determined eligibility criteria and third-party payer decision-making. Each of these processes is ethically complex. First, the medical decision-making: in the interest of justice, it is imperative that transplant teams develop standardized sets of criteria by which patients are selected for HCT. Some of these criteria are straightforward, such as the patient's diagnosis and stage of disease, age, and adequacy of major organ function. Other criteria are more subjective and often relate to psychosocial issues that may influence the patient's ability either to tolerate the HCT procedure or to comply with the long-term follow-up regimen. Multidisciplinary teams are needed that include not only physicians, but also nurses, psychologists, and social workers.

It is important to avoid arbitrary and inconsistent decision-making in deciding when not to offer HCT to a patient. For example, an HCT center may decide that a young patient with acute leukemia who has Down syndrome is not an acceptable candidate because of expected psychosocial management problems that might compromise the outcome. In one survey of 58 pediatric HCT centers, 16 leukemic children with Down syndrome had been transplanted at 10 centers. This was only about 20–25% of the predicted number based on incidence data. In fact, the outcomes were no different than those expected from a similar cohort of patients with acute leukemia who did not have Down syndrome. The author cautioned against physician bias towards these patients [1]. In an accompanying editorial, physicians were advised to use a utilitarian approach, that is, to recommend against HCT for children with Down syndrome only if data show poorer outcomes for them.

Many HCT teams are concerned that patients with a history of active substance abuse may be poor candidates because of expectations of higher complication rates and poor compliance in their long-term care. A retrospective study from one transplant center identified 17 of 468 HCT patients as lifetime substance abusers (alcohol in 71%, marijuana in 30%, and opiates in 30%). When these 17 patients were paired with matched control subjects, a significant difference in survival probability was seen, 60% versus 10% ($p = 0.0022$) [2]. More data may be needed to substantiate these findings, but they do support the current practice at many HCT centers of excluding such patients.

A survey of 597 HCT professionals (physicians, social workers, and nurses) was conducted in which 17 case vignettes were posed

that highlighted a range of psychosocial issues that could potentially impact the long-term outcome of the transplant procedure [3]. The issues included suicidal ideation, use of addictive illicit drugs, and a history of non-compliance. At least 10% of responders indicated that they would not proceed in all 17 vignettes, but there was a lack of unanimity for most of the cases in terms of recommendations to proceed or not. The decision-making seemed contingent on perceptions of the severity and currency of the psychosocial issue and the ability to manage the patient's potential non-compliance.

A challenging case raised the issue of whether an incarcerated minor with relapsed acute leukemia should be offered an HCT, and who should pay for it [4]. This type of case highlights the sharp conflicts between a physician's obligation to provide optimal care versus social justice. Is it cruel and unusual punishment to deny a prisoner a potentially life-saving treatment when the crime was not judged to be severe enough to justify the death penalty? Is it right for the state to pay for such a procedure when other law-abiding citizens without insurance or other resources are denied this type of treatment? There is a need for Federal and state-specific guidelines to establish when it is appropriate medically and socially for prisoners to receive technologically advanced and expensive healthcare.

Decision-making regarding third-party payer reimbursement is seen as a conflict over fairness and justice. Physicians as patient advocates are often in conflict with insurers who argue that HCT for certain diagnoses and disease stages is experimental and unproven. Physicians often believe that it is unfair to have patients accepted or denied access based on geography, their position in society, or their ability to pay when a therapy is investigational, expensive, or both. In analyzing patterns of utilization in four states, Mitchell et al. found that black patients, those enrolled in health maintenance organizations, those covered by Medicaid, and self-pay patients were less likely to receive HCT when admitted for either leukemia or lymphoma [5]. Insurers believe that it is unfair, and uneconomical, to be pressured by physicians and patients to pay for care that is not standard therapy [6].

Uniform and fair methodologies are needed to bridge these two views, rather than relying on costly litigation [7]. One approach is taxonomic, with a treatment modality labeled as experimental or standard. Third-party payers would cover experimental therapy if it met certain criteria, such as a phase III trial approved by the appropriate government agency, for example, the US Food and Drug Administration (FDA), and if the treatment were likely to benefit the patient. The treatment should be medically necessary, safe, and effective. The therapy must be as beneficial as any established alternative, and the improvement must be attainable outside the investigational setting [8].

It is necessary to balance the premature dissemination of poorly studied, toxic, and expensive therapies to desperate patients by accepting limitations to HCT on the one hand, and by accepting that a patient's best interests may be served by an experimental therapy on the other. Legal authorities caution that, although insurers may deny autologous transplant for a patient with cancer because the treatment is experimental, the more relevant question may be, "Is it the best option available for that particular patient with that particular disease?"

The controversy related to autologous HCT for breast cancer over a decade ago exemplifies these dilemmas. Welch and Mogielnicki highlighted some of the lessons that could be gleaned from this experience, including: (1) it is premature to discuss the cost-effectiveness of an intervention when its clinical effectiveness is unknown?; (2) the National Institutes of Health should have an important role in determining what is experimental therapy; (3) public officials should not mandate coverage in the absence of clear data; and (4) the news media watchdog role should be extended to healthcare [9].

An alternative approach is to reach a consensus based on available data of efficacy, duration of expected benefit, and the quality of wellbeing after the treatment [10]. Panels of expert physicians and insurers could review available data on a regular basis and develop grids that designated which diagnoses and disease stages would be covered, based on outcome analyses. Different categories could be considered, such as (1) diseases for which HCT is curative and may be the only curative therapy available, for example, CML; (2) diseases for which HCT may not be curative but definitely prolongs survival, for example, autologous transplant for CML, and possibly breast cancer and multiple myeloma; and (3) diseases for which the benefits of HCT are not yet known, for example, autologous transplant for autoimmune diseases such as multiple sclerosis. One model is the Oregon Medicaid system, which adopted such an approach and covered HCT for all major hematologic malignancies, including chronic lymphocytic leukemia, but did not cover chemotherapy for metastatic renal cell carcinoma. Such an approach is followed in California for Medi-Cal patients and by Blue Cross/Blue Shield. Another component of this approach is to restrict payments to "centers of excellence" that have demonstrated track records in their field.

One of the most difficult challenges that the medical profession and the public at large face is how to assure that progress in developing new therapies will continue in a managed care system designed to minimize healthcare expenses and to reimburse only for medically necessary and proven treatments. Who is going to pay for ongoing research that will lead to the breakthroughs of the future? One could argue that third-party payers have an ethical obligation to participate in this process by helping to underwrite the expenses involved in clinical research, and thereby to help establish which new treatment modalities are in fact effective and superior to established methods. Such new therapies may in fact be cheaper in the long run if they lead to definitive cures for patients and obviate the need for years of expensive, supportive chronic care.

Informed consent for patients undergoing HCT

Case scenario 3

An 18-year-old woman with relapsed acute myelogenous leukemia (AML) has an HLA-matched brother available for allogeneic HCT. She has expressed an interest and willingness to undergo a transplant. However, during the informed consent process, she refuses to listen to any discussion about possible risks and complications from HCT. Can her doctors assume that she has given her consent and proceed to HCT?

Case scenario 4

A 13-year-old girl presents with pancytopenia and is diagnosed with M6 AML. Her physicians recommend treatment with induction chemotherapy followed by allogeneic HCT from a matched sibling or unrelated donor. The patient and her parents are Jehovah's Witnesses and they refuse to accept transfusion of blood products.

Respect for patient autonomy is reflected most critically in the informed consent process, in which patients are informed of their diagnosis, prognosis, potential benefits and risks of the proposed therapy, and alternative treatments available. Although this statement is true for any type of medical intervention, in the setting of HCT there are extra complexities, including the facts that many patients are minors, that almost all patients being considered for HCT have diseases that will likely be fatal without a transplant and are potentially curable with the procedure, and that patients who survive their original disease and the early transplant mortality are at risk for development of a wide variety of chronic complications that may impair their quality of life in many ways.

After a patient has been told that he or she has a fatal disease and that a potentially curative procedure is available, how much does the patient really hear and/or retain about the potential risks and complications? How accurate are the available data about details of mortality and morbidity – including risk of sinusoidal obstructive syndrome (SOS), acute and chronic GVHD, cytomegalovirus and other infections, chronic radiation effects, avascular necrosis, sterility, the risk of second malignancies, and quality of life after transplant – and how many of these data are revealed to prospective HCT patients? If patients choose not to hear all of these specifics and make choices solely on the options of life and death, is this really informed consent? Must we insist on inflicting them with these truths? Can patients exercise their autonomy by choosing not to be fully informed?

Forsyth et al. coined the phrase “decision-making in a crowded room” to describe the process of a patient’s deciding to proceed to allogeneic HCT. This is not a simple, individual cognitive process, but rather a complex, relational interactive process that needs to reflect the multiple roles that an individual plays not only as a patient, but also as a parent, spouse, child, etc. These decisions are “embedded in social relations of obligations and reciprocity” [11].

One study compared the process of informed consent as viewed by physicians or nurses in comparison with the view of patients [12]. For HCT nurses, it was most important that patients know about the side effects and complications of the procedure. The physicians wanted the patients to know about the diagnosis, therapeutic options, and outcomes of treatment. The physicians’ views matched the patients’ most closely, as they made decisions based mainly on outcome and life or death. In another study of adult and pediatric patients and their physicians, the three main reasons why patients and their parents chose HCT were: (1) trust in their physician; (2) fear that their illness would get worse without the transplant; and (3) belief that the HCT would be a cure.

Most of the adult patients remembered that complications could occur, but they could recall fewer than half of those mentioned. Most of the patients believed they had been given adequate information and that it was not too technical, although the physicians thought the information conveyed was in fact too technical and excessive. Most of the patients believed that their physician wanted them to undergo a bone marrow transplantation (BMT), and the patients made their decision based on that advice. One HCT nursing director suggested that the role of the HCT nurse in this process may be to ensure that patients have been completely informed, although the nurse must realize that patients may not be able to comprehend the complex details of treatment, and that the intensity of the choice between life and death may overshadow the risks of potentially life-threatening complications. The nurse can function as a patient advocate, which may create conflicts with the physician at times, and the nurse must not take away hope from the patient [12].

Lee et al. analyzed the degree of concordance or discordance between 313 patients and their physicians in estimating the chances of success after HCT [13]. There was significant concordance between patients and physicians when the outcomes were likely to be favorable, but when patients had more advanced disease, they tended to fail to recognize the higher risks of relapse and death. The authors speculated that physicians may tend to minimize the risks in their discussions with patients who have advanced disease. Divulging more information about these risks may not change the patients’ decisions to move forward with the HCT, but it may promote better psychologic adjustment after HCT.

Andrykowski et al. focused on the question of whether patients had “returned to normal” following HCT, and examined differences between their expectations and actual outcomes, and the impact that these differences might have on their sense of wellbeing [14]. They studied 172 disease-free survivors from five HCT centers and found that only a minority felt they were back to normal. Before HCT, only 19% of patients had not expected to return to normal, and 47% anticipated they would. Following HCT, 32% (possibly up to 52%) stated that they had not returned to normal. The discordance between pre-HCT expectations and their current functional status was associated with greater current psychologic stress. Despite this discrepancy, the survivors’ evaluation of their decision to pursue HCT was generally fairly positive.

The issue of involving children in medical decision-making is important since many candidates for HCT are minors. Most investigators recognize that children’s capacity for decision-making and autonomy develops over time. The parents or guardians must give consent for their minor child, but the wishes and concerns of the child should be taken into account [15]. The American Academy of Pediatricians states that one “should not exclude children and adolescents from decision-making without persuasive reasons” [16]. It is generally accepted that, starting at 7 or 8 years of age, children are capable of giving assent to any proposed intervention, and that their assent should be required in order to proceed. The assumption is made that the parents will act as surrogate decision-makers for their children and make choices based on the best interests of the child. The courts may need to become involved if parents do not seem to be following this approach, as in case scenario 4 if a parent is a Jehovah’s Witness and refuses blood transfusion for the child.

Informed consent for donors of hematopoietic cells

Case scenario 5

A mother leaves the country with her 16-year-old son who is HLA matched with his 22-year-old brother who has acute leukemia, because she fears that if her younger son donates stem cells then he will die or also get leukemia. She feels that she is going to lose one son and does not want to lose the other. The older son dies from refractory leukemia without HCT.

Case scenario 6

In performing HLA typing on members of a large family because a relative has leukemia, it becomes evident that one of the siblings has a different father from the rest of the children.

The source of cells for an allogeneic transplant is usually a living donor who may be closely related to the patient, who may be a minor, or who may be an unrelated volunteer. In each of these situations, the autonomy of the donor must be respected, as reflected in an appropriate informed consent process. Donors must be informed of the specifics of the procedure that they may undergo, especially the potential risks involved. The process must be free of coercion and must respect the confidentiality of the donor and the family when it is a family donor in question. Cultural diversity issues may complicate the search for a potential donor if unusual or irrational beliefs are brought to bear. Strict confidentiality related to HLA typing results must be maintained to protect the privacy of all potential donors, including the possibility that previously hidden facts about paternity may be brought to light to an unsuspecting family. Revelation of such information could have devastating effects on the entire family unit.

Special and important considerations are raised when the donor is a minor. It is generally accepted that the risks involved in being a marrow donor are very small. Estimates of the incidence of life-threatening or incapacitating complications are about 0.29% for adult donors at several centers and 0.4% in a pediatric population from a single institution [17]. The European Group for Blood and Marrow Transplantation reviewed 27,770 bone marrow collections from 1993 to 2005 and found only one fatal event (pulmonary embolism) and 12 serious adverse events, mostly cardiac [18]. A potential benefit of the donation process is that pre-existing medical problems that require intervention may be detected in the donor. In this study in Seattle, 206 medical problems were observed in the 1549 donor evaluations, with hypertension, obesity, and cardiac problems the most common (see Chapter 42) [19].

Many collection centers are using granulocyte colony-stimulating factor (G-CSF) mobilized peripheral blood cells (PBCs) from matched siblings or unrelated donors as their preferred source of cells [20–22]. Many of the risks associated with marrow harvests are minimized or prevented, such as complications from general anesthesia, the pain from multiple iliac crest punctures, local hematomas, and/or infection at the aspiration sites. The use of G-CSF for this purpose is considered to be generally safe except for donors who have certain underlying medical conditions such as hemoglobinopathies, autoimmune disease, or coronary artery disease.

In a randomized study comparing PBC with bone marrow donations, the donors found the PBC collections to be the less burdensome and preferred method [23]. In a study of sibling donors for patients enrolled in a randomized trial comparing PBCs with bone marrow cells, Rowley et al. found that the intensity and nature of pain were very similar for the two groups, although all the PBC donors returned to normal function by 14 days compared with 80% of the bone marrow cell donors [24]. It is still not settled whether there is any overall advantage to the recipient from one source of cells over the other. Donor preference may be the deciding factor if there is no clear advantage between the two cell sources.

In reviewing the experiences and attitudes of the first 20 volunteer unrelated donors at the University of Minnesota, Stroncek et al. found no serious physical or emotional after effects [25]. Nine of the 20 donors reported that a friend or family member had discouraged them. Nineteen said they would donate again, and 17 would advise others to donate.

The benefits of being a marrow donor for a family member or an unrelated recipient are a matter of debate. At one extreme, it is argued that there are no benefits to the donor, and therefore even the small risk of complications becomes more significant. Others state strongly that there are remarkable benefits to the donor of a psychologic nature, especially when donating to a family member, such as the satisfaction of helping to save a loved one's life [26]. On balance, the very low risks associated with marrow donation and the fact that marrow is a renewable resource like blood, and that significant benefits are derived by the donor, make it ethically appropriate to encourage PBC and marrow donation.

Of course, it is imperative that any coercion of potential donors be avoided. To that end, the HCT center should keep results of HLA typing confidential (or not even initiate testing) until all family members have had the opportunity to discuss privately their desire to proceed [12]. To protect further the rights of a potential related donor, the current edition of the Foundation for the Accreditation of Cellular Therapy–Joint Accreditation Committee of the International Society for Cellular Therapy and European Group for Blood and Marrow Transplantation (FACT–JACIE) *International Standards for Cellular Therapy*, Standard B6.3.1.2 now requires that "allogeneic donor suitability should be evaluated by a licensed healthcare professional who is not the primary transplant physician or healthcare professional overseeing care of the recipient" [27]. This has been the standard practice for consenting of minor related donors and adult unrelated donors for many years.

The psychologic state of the donor must be respected. If the outcome is poor, especially if the patient fails because of GVHD, there will be a natural tendency for donors to blame themselves for the patient's death. Appropriate counseling before and after the HCT can help lessen this burden for the donor. In light of these concerns, it has become the legal standard that no court can force anyone to undergo medical testing or a procedure that is intended only to benefit another individual.

Confidentiality and non-coercion are especially important issues in relation to unrelated donors. The National Marrow Donor Program has very explicit policies and procedures designed to respect potential donors' autonomy by requiring informed consent at every step of the process, including the time at which a donor is first listed in the registry; before collection of blood for confirmatory typing, infectious disease markers, and research samples; prior to notification of the transplant center that a donor is willing to proceed to donation; and before general anesthesia [28].

The donor's privacy is of the utmost importance to avoid any extraneous influences or pressures as the donor decides whether or not to donate. The identity of the donor is known only to the individual donor center, and many precautions are put in place to ensure this. Generally, the recipient and donor are allowed to contact each other directly only by mutual consent 1 year after the HCT. The National Marrow Donor Program considers these measures to be critical in promoting increased participation in the program by altruistic individuals. The World Marrow Donor Association reviewed the ethical issues for unrelated donors, focusing on respect for the donors' autonomy, wellbeing, and needs. They stressed the importance of non-coercion and adequate informed consent, especially when requests for donation of a second cellular product are being considered [29].

The process by which decisions are made to use minors as marrow donors is somewhat controversial [30–32]. Some authors have questioned the manner in which informed consent is obtained to collect marrow from minors and have asked whether parents can truly give informed consent. The need to involve the minor in the consent process by seeking his or her assent is a widely accepted concept, especially for children over the age of 7–8 years. The American Academy pf Pediatrics Committee on Bioethics has developed five criteria that must be met for the ethical utilization of a minor sibling donor: (1) a medically equivalent adult donor must not be available; (2) an actual or anticipated strong personal and positive emotional relationship between the donor and recipient must exist; (3) there is a significant likelihood that the recipient will benefit; (4) the clinical, emotional, and psychologic risks to the donor must be minimized; and (5) parental consent and the child's assent must be given [33,34].

Delany, in an article with several separate contributions, questioned whether it is really legal to harvest marrow from a minor and labeled the process "altruism by proxy" [32]. One legal concept permits a medical procedure only if it serves the best interests of the child who undergoes it. If there is disagreement between caregivers, it may be necessary to go to court. A second concept argues that parents can give valid consent to treatments that are "not against the interests of the child." This approach was developed to allow blood drawing from children whose legitimacy or parentage was at issue. Some have argued that this principle is relevant to any medical intervention carried out on children purely for other people's benefit.

Delany argued that marrow donation is not in the best interests of the donor, and that it may be against the child's interests, especially if the potential donor is too young to have established an emotional bond with the intended recipient. She also contended that the parents are not well suited to give informed consent for the donor owing to conflict of interests related to the sick child, and that an informal tribunal or other forum independent of the parents and medical advisors should be responsible for approving each proposed donation. This procedure would be analogous to the strategy developed by the Law Commission of England and Wales to safeguard mentally incapacitated adults from being inappropriately volunteered for marrow extraction.

Month, in the same joint article, disagreed strongly with this interpretation of the issues [32]. She believed that the positive aspects for the child donor are considerable and include the saving of a sibling's life and the benefit of many years of a whole family not burdened by the psychologic trauma of the death of a child. Further, since HCT is an accepted therapeutic option that can be lifesaving, and often offers the best cure rate, is there really any reason a morally competent sibling would not want to donate? The risks of donation are minimal, especially when compared with the risks of not donating marrow, that is, the death of a sibling.

Lyons described the donation of stem cells by a minor to a sibling as "the appropriation of bodily tissue from one unconsenting human and its conveyance to a third, albeit related, party." He challenged the legality of this exercise of power by the parents. He argued that for parental consent to be "legally permissible, it must be on the basis of an implicitly acknowledged property right in the (donor) child" [35].

Savulescu, in the cited joint article [32], argued that although the bone marrow donation is not in the donor's medical interests, it may be in his or her overall interest. To save the life of a loved one is one of the most important things one can do. Even for donors who are too young to understand at the time, the potential for a future sense of achievement and the love and gratitude of the saved sibling is important. There are also benefits to the family unit. Parents should be the ones to give informed consent after they are educated about the risks and benefits of the donation, just as parents often make decisions with conflicting interests of their children, but with a commitment to the overall good of the family.

An unusually difficult case was published involving a 15-year-old boy with relapsed AML who was incarcerated for sexually assaulting his 9-year-old sister [4]. The conflicts involved in the decision-making about whether or not to offer the boy HCT were discussed in a preceding section. The 9-year-old sister was the only HLA-matched relative available. Should she be asked to donate stem cells to her brother? Is there a reasonable alternative source of stem cells available for the patient, for example, a matched unrelated donor? Is the mother the right person to give informed consent on her behalf? Should there be a legal guardian appointed to protect the interests of the sister? Would the potential harm to her, psychologic and physical, outweigh the benefits? Although these are questions relevant to almost every case involving a minor donor, the conflicts were clearly more acute in this case.

The formal process for approving the use of a minor for marrow donation varies between countries and between centers within the same country. A survey of 52 HCT centers in Europe and the United States found that some centers had an ethics committee decide the validity of the therapeutic proposal [31]. In France, there is a law that requires a committee of three experts to assess the psychologic and medical consequences of donation of the organ by a minor, and notes that "the refusal of the minor donor to accept the removal shall always be respected." In the United States, a Washington State court ruling stated that the advantages to the donor are undoubtedly greater than the risks, and defers to the parents to give informed consent. Some institutions require an authority outside the family and hospital, for example, a "tutelary judge" or commission of experts, to make the decision.

A questionnaire was sent to 70 HCT centers in North America by pediatricians at the M.D. Anderson Cancer Center to poll the HCT teams on their approaches to marrow donations by minors [36]. The impetus for sending the questionnaire was a case brought to the M.D. Anderson pediatricians in which they were asked to collect marrow from a young child to be donated to the child's parent. There was a significant difference in size between the child and parent, and three HLA mismatches. The parent had relapsed AML. Ethical concerns were raised by hospital staff members. As a result, the M.D. Anderson Center developed a process in which the minor donor and surrogate are interviewed by a social worker, pediatrician, and anesthesiologist, none of whom is involved in the care of the recipient. If any concerns are raised, the case is referred to the ethics committee for consultation.

Fifty-six (80%) of the centers responded to the questionnaire. There was consensus in endorsing the validity of parental consent. Most centers would use donors as young as 6 months old and would use them more than once if needed. The centers were willing to use minor donors for patients on experimental protocols, and the projected outcome of the HCT did not affect the decision to use the minor as a donor. Issues raised included the non-therapeutic nature of the donation, the vulnerability of the minor, and the potential conflict of interest when a parent acts as a surrogate for both the donor and a sick family member. Even greater conflict was seen if a parent was the intended recipient of the marrow, and most agreed that the other parent or both should be involved in the informed consent procedure.

The majority of the centers and physicians had policies or practices of using the parents as the surrogate; a minority preferred to use a parent plus a child advocate or child protection agency. If there were disagreements between the parents, eight centers would cancel the HCT, and the rest would either seek consultation with the ethics committee, use an unrelated donor, refer the parents for another opinion, or refer the decision to a child protection agency. When asked if the use of a child intentionally conceived as a marrow donor was ethical, most of the physicians answered that they would be willing to use such a donor. They would consider using umbilical cord blood (UCB) in that case as being safer for the donor.

The participation of pediatric donors in clinical research raises additional issues beyond standard clinical practice [37]. When can Institutional Review Boards (IRBs) approve such activities? The IRB must focus on whether the proposed research procedure is different for the donor compared with a standard stem-cell collection. If the proposed research adds or replaces procedures to the standard clinical donation, and thereby increases the risks to the donor, such a protocol must be approved by the Secretary of Health and Human Services with the advice of a panel of experts (category 46.407 of the Federal Regulations). Some have argued that minors who are asked to donate G-CSF-primed PBC should be considered to be research subjects, since the data about long-term risks in this setting are not well known. The parents would be the best persons to decide for their child donors, but IRB approval would be required [17,38].

The participation of unrelated donors in research activities is also an issue of concern in terms of advancing the science of such transplants, and protecting the rights of these altruistic individuals. There must be efficient mechanisms in place to ensure that research review boards approve such protocols in the countries of both the donor and recipients. The World Marrow Donor Association has called on all donor registries to participate in research acitivities that can lead to improved outcomes for patients and to clearly define what constitutes research versus standard clinical practice. King et al. cautioned that the health and wellbeing of the donor must take precedence over the interests of science and society [39]. Donors must be carefully informed about what will be done with their cells, especially if there is any intended use for research purposes [39,40].

Alternative sources of hematopoietic cells

Case scenario 7

A couple decides to reverse a vasectomy to create a new baby to be a possible donor for their teenage daughter with CML who has no family or unrelated donors.

HLA-matched siblings are usually considered to be the primary source of cells for HCT. For the 70% of patients who lack such a donor, alternative sources of stem cells include matched related donors other than siblings, unrelated volunteer donors, UCB cells, and possibly autologous stem cells in the appropriate clinical setting. In this section, the ethical issues raised by two potential sources of stem cells are discussed, namely UCB [15,41–43] (see Chapter 39) and "children conceived to give life" [44] or so-called "savior siblings"[45,46].

The advantages of cord blood over adult marrow include the lower risk of carrying viruses, a reduction in procurement time from the 4–6 months needed for an unrelated marrow donor to 1–2 weeks, and the fact that cord blood cells are potentially usable across greater HLA disparities. The major disadvantages are the limited number of cells available, the fact that one cannot go back to the donor for more cells if needed, and the risk of transmitting a genetic disease not previously diagnosed in the donor's family.

Marshall raised several ethical issues related to cord blood cell collections and cord blood banks, starting with consent and privacy [47]. Is informed consent required for a product that is otherwise discarded as waste? Is the mother (or parents) the appropriate one(s) to give consent? Is consent required to conduct a battery of tests to detect possible infectious or genetic diseases, or both? Should donors, that is, the parents, be informed of the results of such tests? Who owns the cord blood? Obviously, the donor themself cannot give informed consent, yet an extensive medical profile about the donor may be generated, raising concerns about invasion of privacy. Should consent be obtained for follow-up tests that are not consented to directly? What should be done with abnormal results from such tests? Should banks maintain medical files and genetic data, but in such a way that names and identifiers are delinked from the donated sample [48]? What are the obligations to inform the family if evidence of human immune deficiency virus or an abnormal gene is found?

Some authors argue that the infant donors should be the first to benefit from use of their own cord blood cells [49]. Records should be kept of diseases detected and parents informed. Therapy should be offered for treatable diseases. Commercialization of cord blood cells for therapy should include a financial benefit for infants; for example, royalties from each donation should be placed in a national trust fund for research and treatment of children with serious diseases. Kurtzberg et al. argued that cord blood that was previously discarded material should be a public resource with no financial gain to any party [50]. Regulation of donor banks by an agency such as the FDA is needed. For example, there are companies that try to persuade parents that they should store the cells as insurance against future needs, when in fact the chances are remote that the donor would ever need or want to use the cord blood cells. There is a pressing need to protect the confidentiality of the information collected, to notify parents and children of the test results, and to assure equitable access to cord blood samples. For the health of the mother and baby, the collection process should be restricted to full-term, uncomplicated pregnancies, and should not interfere with good obstetrical practice at delivery.

The American Academy of Pediatrics has addressed the issue of cord blood banking and issued a set of guidelines to help physicians regarding types and quality of blood banks (for-profit versus not-for-profit), ethical and operational standards including informed consent policies, financial disclosures, and conflict-of-interest policies [51]. Their three main recommendations are: (1) the storage of cord blood in private banks for later personal or family use should be discouraged unless there is a full sibling in the family with a known malignant or genetic condition that might benefit from cord blood transplantation; (2) cord blood donations should be encouraged when stored in a bank available for public use; and (3) private storage of cord blood as "biologic insurance" should be discouraged.

Considerable attention and debate were generated in response to the actual case outlined above as case scenario 6. The practice of "conceiving a child to give life" is not a rare event [52,53]. Some question whether a good outcome for the recipient lessens the ethical dilemmas posed. It was argued that such a practice does not impose harm on persons or relationships within the family, and does not show lack of respect for the child conceived [12]. Others raised their concerns about performing prenatal testing to diagnose the genetic disease affecting the intended recipient and for HLA typing, and the potential for aborting in the case of a mismatch.

One hematologist's view of the concept is that such a child is conceived not to replace the sick sibling, but to give life to the sibling who would not survive without a transplant [53]. The benefits of this approach include the fact that the cord blood is disposable material, and that no anesthesia or blood transfusions are needed for the donor. From the recipient's perspective, the transplant can be performed earlier since a marrow transplant could require a delay of 6 months or more.

Alby described three characteristics of pregnancies conceived for HCT: (1) families in that situation face the trauma of the impending death of the sick child; (2) the pregnancy outcome with respect to HLA matching and the HCT results are both uncertain; and (3) biology has intruded into the family dynamics [44]. A family may attempt a cure at any cost, especially in an emergent situation such as acute leukemia. A child may be viewed subconsciously as a replacement child, but should never be reduced to the role of a therapeutic tool. In terms of family dynamics, a child may be viewed as bad or good based on HLA matching. Many are concerned that such a child is being conceived only for transplantation. Yet a child is always born for something: to maintain the integrity of a couple, to gratify the parents' need for a family, to repair their vulnerability. All parents must go beyond the idealized view of their children and accept that they have an identity of their own, and all children have some symbolic role in the family fantasy. In that light, is there really anything wrong with conceiving a child to donate cells for the purpose of saving the life of a sibling?

Advances in in vitro fertilization techniques have opened the door to preimplantation genetic diagnosis (PGD). Candidate embryos can be screened in vitro for HLA matching [54] and for various genetic traits [55–57] as the basis for selecting which embryos to implant. HLA typing of embryos to select a potential stem cell donor for an afflicted relative has been proposed as a legitimate means of securing a donor for a patient who is in need of a lifesaving transplant.

The ethics of this approach have been reviewed, and the conclusions were that using PGD to choose a stem-cell donor is unlikely to cause harm to anyone, is likely to be beneficial to some, is a reasonable use of limited health resources, and should be permitted in countries where PGD is already allowed [58]. Morgan et al. also concluded that the use of assisted reproductive techniques to create a stem-cell donor can be considered to be ethically acceptable [59]. As a case in point, in the United Kingdom, the Human Fertilisation and Embryology Authority gave permission for PGD to be utilized to select an unaffected embryo to serve as a future hematopoietic cell donor for a sibling with thalassemia [60]. The technique has been used in the United States since 2000. Pennings et al. argued that PGD-guided selection of embryos for this purpose is morally defensible on the condition that the procedure to be performed on the future child is acceptable for an existing child, and that the "instrumentalization" of the donor child does not demonstrate disrespect for the child's autonomy and intrinsic worth [61].

Devolder considered the risks and benefits of utilizing preimplantation HLA typing for selecting embryos to be used as donors of stem cells for sick siblings and concluded that it would be unethical not to allow this procedure, since there is no indication of harm to the donor child, and some lives would be saved [62]. She argued further that it should be up to the parents to decide whether their current or *future* children can act as a donor for a loved one, and that the pool of potential recipients should not be restricted to siblings or other family members, but should be expanded to include anyone whom the couple loves.

The ability to create multipotential stem cells in vitro from pluripotential embryonic stem cells is a subject of wide public debate. Legal and ethical distinctions have been drawn between human reproductive cloning and nuclear transplantation for the production of stem cells for therapeutic applications. Only the latter will be discussed here as a potential source of hematopoietic cells for use in HCT in the future. Many scientists, ethicists, government bodies, and medical organizations in the United States, Canada, and Europe have advocated for the legalization of research for the purpose of therapeutic cloning [63–68]. The potential to utilize such cells to treat a variety of medical conditions appears to be great, although significant technical hurdles are yet to be overcome before there can be clinical applications. Many serious ethical issues must be considered, including the protection of human dignity, the source of unfertilized eggs and/or embryos to be used for research, informed consent from potential donors, the privacy of donors, and financial incentives to donate eggs and/or embryos.

Transplantation for non-malignant diseases

Most HCT procedures are performed to treat malignant diseases for which HCT often represents the only curative option. Many non-malignant diseases are also treated by HCT, especially in the pediatric patient population, and include primary marrow failure such as severe aplastic anemia and a variety of congenital immune deficiency syndromes (see Chapters 71–76). The balance of risk and benefit for patients with these diseases is clearly in favor of HCT since the diseases are often rapidly fatal, and curative alternative options are generally not available.

The balance may not be so clearly defined for a variety of diseases that affect marrow-derived cells, which may be a source of significant morbidity for affected patients and possibly shortened life span, but are not considered to be rapidly fatal. Further, the data that demonstrate the long-term benefit from HCT for these conditions may be inconclusive or even non-existent. Examples of this category of diseases include hemoglobinopathies such as sickle cell disease, certain metabolic storage diseases, autoimmune diseases such as multiple sclerosis and rheumatoid arthritis, and acquired immune deficiency diseases, specifically AIDS. How does one select the right patient to be treated by a procedure that carries significant risk of morbidity and possibly early mortality? How can one demonstrate the efficacy of HCT in diseases that usually progress over years rather than weeks or months? How does a parent decide to consent to an HCT for a child with such a disease?

This discussion focuses on hemoglobinopathies as a paradigm for these issues since there has already been a broad experience in performing transplants for thalassemia [69], and a body of literature about the ethical dilemmas involved is available. These issues were discussed at an international meeting on HCT in children held in March 1994 [41]. With regard to hemoglobinopathies, the difficult questions are whom to treat and when, and whether to offer HCT as a curative procedure to all affected children as early as possible. Some participants favored HCT for all patients with sickle cell disease who have an HLA-matched sibling in early childhood, given the high risk of morbidity in adult life. Others argued that it should be reserved for those who show clinical indicators of poor prognosis, as adopted by the ongoing national trial to recruit 30–60 children over a 5-year period. For thalassemia, the clinical course is more variable. Some proposed that HCT should be offered before any morbidity has occurred, whereas others would reserve it for children whose iron overload was well controlled and who were without liver disease.

Giardini discussed the ethical issues of HCT for thalassemia in an editorial in 1995 [70]. He argued in favor of HCT since the risk of mortality from disease-related complications remains high even with desferrioxamine chelation. Giardini argued that it is ethically and economically appropriate to recommend HCT for thalassemia, especially given the progress in dealing with GVHD and cytomegalovirus, the availability of newer antibiotics, and so forth; and the fact is that currently HCT offers the only chance of cure of the disease.

Kamani et al. reviewed several issues related to HCT in the pediatric population [71]. They posed three questions that need to be addressed when considering allogeneic HCT for non-malignant diseases in children such as hemoglobinopathies. These were: (1) how bad is the health quality of life for affected patients?; (2) are there prognostic factors to predict who is likely to suffer serious complications from the underlying disease?; and (3) what is the likelihood of success from the HCT in light of the quality of the matched donor available? More data are needed to answer the second question in particular to help select candidate patients in a way that would improve the risk/benefit balance of this approach.

Kodish et al. examined the issue of parents' decision-making concerning HCT for children who were affected with sickle cell disease [72]. A questionnaire was presented to parents with hypothetical chances of cure versus mortality to see how they balanced these two outcomes. In the study of 67 parents, 54% were willing to accept some risk of short-term mortality, 37% would accept at least a 15% mortality risk in the short term, and 12% were willing to accept a 50% or more risk. Sixteen (24%) of the 67 parents would not accept HCT even if there was a 0% mortality risk.

Differences were found between the group of parents who would accept some risk and those who would not. Parents who were high-school graduates, who were employed outside the home, or who had more than one child with sickle cell disease were more willing to take the risks. Of note, parents were more willing to take risks for girls than for boys. The parents' decisions were not related to the clinical severity of their children's illness, unlike the way the doctors might make such a decision. For parents with more than one child, their willingness may reflect their knowledge of the disease, or the burden of caring for children with sickle cell disease. Clearly, the concerns and values of the parents must be considered along with weighing the medical issues of risks and benefits.

In a recent report by Hansbury et al., a cohort of 113 pediatric patients with sickle cell disease receiving chronic transfusions was analyzed with respect to options and preferences for allogeneic HCT [73]. Forty of these patients had unaffected full siblings who could possibly serve as a stem-cell donor. The families of 23 of these 40 patients agreed to HLA type the sibling(s) and eight of these 23 were matched. Only three of these eight underwent HCT. The reasons for declining HLA typing or HCT included fear of toxicities, inadequate support for the procedure, including time and resources, and belief that the current transfusion therapy was adequate.

Recent advances in HCT, such as the use of peripheral blood or umbilical cord blood hematopoietic cells from allogeneic donors and reduced-intensity conditioning regimens, have been utilized in the treatment of hemoglobinopathies [74–76]. These advances help reduce the risks of short- and long-term toxicities for either the donor or the recipient, and thus create a more favorable risk/benefit ratio. Parents of minors with hemoglobinopathies will need to be informed about these innovations to help them make an appropriate decision for their children who may be candidates for HCT.

End-of-life issues

Case scenario 8

A 50-year-old physician with CML is dying from SOS and GVHD with liver and respiratory failure early after HCT. He has no written advanced directive. He made his second wife promise that she would not let him stay on life support for more than 1 week if he had no hope of recovery. She is devoutly Catholic, but feels she made a commitment to her husband to withdraw life support. His adult children from his first marriage, who are atheists, say their father would never agree to withdrawal of life support, that he is ardently opposed to euthanasia, and that to him withdrawal of life support is no different from euthanasia.

Respect for patient autonomy requires caregivers to determine the wishes of their patient with respect to resuscitation and life support. Advanced directives, such as a Power of Attorney for Health Care, are extremely effective vehicles to facilitate discussions between patients and their doctors, for patients to convey their wishes, and to name a surrogate to speak for them when they become incapacitated.

A new type of document called Physician Orders for Life Sustaining Treatment (POLST) has been developed to augment other traditional methods of advance care planning [77,78]. Currently 34 states either have or are developing POLSTs. Unlike Do Not Resuscitate (DNR) orders, these documents allow patients to specify their treatment preferences before the event of a cardiopulmonary arrest. POLSTs are particularly helpful for elderly or incapacitated patients who may be shuttled between various nursing homes and hospitals with many different healthcare providers involved in their care.

Yet very few patients execute such documents or discuss these matters with their doctor. Such discussions about end-of-life issues are difficult for most physicians, nurses, and patients. They are even more difficult in the context of HCT, where the patients are generally young and, although they have potentially fatal diseases, often have a significant chance for cure with this treatment. During the informed consent process that leads up to the HCT, physicians are obligated to discuss the risks and complications of the planned therapy, including the chance of early mortality. As discussed above in the section on informed consent for patients, when faced with life and death choices, patients often block out the details of possible complications in the decision-making process. Physicians have trouble raising end-of-life issues in the context of proposing a potentially lifesaving therapy, in part for fear that patients will take away a negative message about their prognosis [79].

The fact remains that up to 15–20% of patients may succumb to early allogeneic transplant-related mortality. HCT patients often decompensate rapidly and unpredictably, for example, from severe SOS or GVHD. There may not be an opportunity to discuss end-of-life issues when the patient is in respiratory failure on the way to the intensive care unit. The quality of patient care would be much enhanced if such discussions and appropriate documentation of patients' wishes were carried out well before this point, and were then acted upon as dictated by the patient or the surrogate. Many of these patients will be maintained by intensive life support for extended periods of time, despite generally poor chances of recovery. Some centers have developed ICU admission policies that exclude HCT patients who meet certain criteria, such as critically ill patients who have relapsed disease with no treatment option for their malignancy, multiorgan system failure with respiratory failure unresponsive to standard treatments short of intubation, and refractory grade III–IV acute GVHD with respiratory failure requiring intubation. For those patients who are admitted to the ICU, it is imperative to update their surrogates/families on a regular basis with multidisciplinary meetings. The caregivers need to discuss current status in addition to short-term goals of ongoing therapy, and then reassess the patient's progress towards those goals every few days. At some point in the course of the ICU stay, the goals of therapy must shift from cure and aggressive interventions to palliation and supportive care for a dying patient. Caregivers are obligated to recommend when it is time to do so based on the principles of patient autonomy and non-maleficense. Rigorous attention to pain control is essential throughout the HCT process and certainly during the period of dying.

The principles of fidelity and non-abandonment require caregivers to make it clear to patients and their families that they will not be abandoned as the goals of treatment shift from cure to caring for the dying patient. Although it may be appropriate to withhold interventions that are medically futile or ineffective, how is this to be determined? How much of our limited healthcare resources should be expended providing what is ultimately futile medical care? How great an emotional cost do families have to pay? These are difficult questions that need to be addressed at both the macrolevel of society and the microlevel of individual patients and families. It is the patient (or surrogate) who is best able to understand and decide on the issues of his or her ability to pay for a treatment and the possibility of financial destitution of a family by continuing futile care. The surrogate must utilize substituted judgment to relay the decisions that the patient would have made if he or she had the capacity to do so. In cases in which no surrogate is legally designated, an ethics committee may need to be involved to consider quality of life issues and death with dignity.

To explore the variables involved in instituting DNR orders for HCT patients, a retrospective review of 40 patients who died in the Seattle Veterans Administration Medical Center HCT unit was carried out [80]. This center has a DNR policy that requires physicians to document the discussion held with the patient/surrogate, and for the patient/surrogate to sign a DNR consent. Patients with fatal diseases often suspend their feelings about terminal illness in the hope of a cure through HCT. The dying trajectory of these patients is often sudden and unpredictable. The healthcare providers often focus on aggressive medical management when these situations arise and, as a result, the topic of death is avoided. The process of executing DNR orders was believed to facilitate the transition from aggressive care to supportive care in critically ill HCT patients.

In 11 studies of HCT patients who required mechanical ventilation, the rates of survival to discharge from the hospital ranged from 0% to 11.1%, with a mean of 4.7% [81]. It would be clinically useful to define a subgroup of patients whose chance of survival is so low that both patients/surrogates and physicians can agree that intensive care can no longer fulfill the original goals of the HCT. Criteria to identify patients who are destined to die after HCT are needed to help reduce emotional and financial expenditures of families and institutions. At the Fred Hutchinson Cancer Research Center from 1980 to 1992, 25% of all HCT patients were ventilated. Patients who were more than 20 years old, had disease in relapse, and had grafts that were not HLA identical had a 50% chance of needing ventilation. Only 6.1% survived. To identify predictors of death in mechanically ventilated HCT patients, Rubenfeld and Crawford conducted a nested case–control study comparing all 53 survivors of ventilatory support with 106 matched control subjects who did not survive [81]. These patients were selected from the 865 individuals who were mechanically ventilated for at least 24 hours during that 12-year period. Survivors were defined as those who were alive for 30 days after extubation and who were discharged from the hospital.

Survival was statistically associated with younger age, lower score on the APACHE (Acute Physiology, Age, Chronic Health Evaluation) III scale, and shorter time from HCT to intubation. Of the 106 control subjects who died, 82% died while on the ventilator, and the remaining 18% died in the hospital a median of 18 days after extubation. Of the 53 survivors, median survival after extubation was 634 days (range 54 days to 12 years). Eighteen (34%) survived for less than 6 months and five (9%) for less than 1 year; 30 (57%) lived for more than 1 year. No patient who was intubated for more than 149 days survived. The survival rates changed from 5% to 16% over the most recent 5 years, which was not explained by changes in the age of patients, the rate or timing of intubation, or the percentage of allogeneic transplants that were not HLA identical. The improved survival may be due to better antimicrobials and the use of cytokines.

There were no survivors among the 398 patients who had lung injury and either required more than 4 hours of vasopressors or had sustained hepatic and renal failure. Using these three criteria, an accurate prediction of death could be made in the first 4 days for more than half of the patients who did not survive. Of the 60% of patients who developed any two of these three risk factors, half had done so by day 2 and 90% by day 4. On average, these risk factors developed six ventilator days and nine hospital days before death. If life support had been withdrawn on the first day that two out of three risk factors were met, and if death had followed swiftly, more than 7300 hospital days and 4800 ventilator days could have been avoided for the 812 patients who died.

A multi-institutional study confirmed these observations in adult HCT patients, for whom the combination of mechanical ventilation and hepatic and renal dysfunction was associated with a probability of death of 98–100% [82]. This experience was confirmed in a recent report from a single institution which reviewed the outcomes for 68 patients who required mechanical ventilation after allogeneic HCT [83]. The overall mortality rate was 86.8%. The Sequential (or sepsis-related) Organ Failure Score (SOFA) [84] was used to predict mortality in this group of patients. The SOFA score assesses the function of six major organs and generates a score of 0 to 24. The mean SOFA score for surviving patients was 7.7 and for non-survivors it was 11.6 ($p = 0.009$). The presence of renal failure or liver dysfunction at the time of intubation was associated with a 100% mortality rate, as was reported previously by Rubenfeld and Crawford [81]. The SOFA score on the day of admission to the ICU was also predictive of survival in other studies in Germany [85] and Sweden [86]. A study in Belgium confirmed the poor prognosis for allogeneic HCT patients who require intensive care [87]. The overall ICU mortality, in-hospital mortality and 6-month mortality rates were 61, 75, and 80%, respectively. Bacterial infection as a the cause of multiorgan failure was associated with a lower mortality rate compared with other causes.

A scoring system for pediatric patients undergoing allogeneic HCT called the Oncologic Pediatric Risk of Mortality (O-PRISM) may be useful in predicting fatal events, and thus help parents decide to establish a supportive care strategy for their children [88]. Outcomes for pediatric patients who require mechanical ventilation after allogeneic HCT may be somewhat better than for adult patients. In a study in The Netherlands [89], 35 out of 150 patients required mechanical ventilation between 1999 and 2007. The case fatality rate was 42%, and mortality was associated with multiorgan failure on day 2 of ICU admission, and with the use of high-frequency oscillatory ventilation. The 6-month survival for patients discharged from the ICU was 82%.

Although most physicians and ethicists may agree that futile, inappropriate, or ineffective medical care should not be provided even if requested, how are these terms to be defined, and by whom? In cases in which the patient/surrogate continues to request treatments that the caregivers consider futile, the physician is not ethically required to provide that care, but is obligated based on the principle of non-abandonment to facilitate the transfer of the patient to another physician who will. Consultation with the institutional ethics committee may be helpful in these most difficult situations. Several medical and legal societies such as the AMA, CMA in California [90] and LACMA/LACBA in Los Angeles County have published guidelines or policies stating that physicians are not obligated to provide care that is considered medically ineffective by community standards. Some medical centers have policies and procedures to define the process by which conflicts arising over medically ineffective care will be managed. In cases where patients/families demand treatments that the healthcare team deems to be medically ineffective, a sequence of steps is initiated including consultation with other physicians and the ethics committee. If there is still disagreement, then the burden falls on the family to seek a court injunction in a timely manner to stop the withdrawal of life-sustaining treatments.

Conclusion

The indications for HCT have expanded over the years to encompass a wide range of diagnoses and disease stages, including patients with early stages of hematologic malignancies considered to be at high risk for relapse, solid tumors, congenital disorders, and autoimmune diseases. Potential sources of stem cells have also expanded to include autologous and allogeneic cells from bone marrow, peripheral blood, and cord blood from related or unrelated HLA-matched donors. It is imperative that the rights of both patients and donors be respected in step with these technologic advances. The ethical principle of justice requires caregivers and insurers to provide potentially life-saving yet high-risk procedures to HCT candidates in an open and equitable manner. Patient autonomy, non-maleficence, and non-abandonment are guiding principles in making decisions about end-of-life care.

CHAPTER 32

Psychosocial Issues in Hematopoietic Cell Transplantation

Richard P. McQuellon and Katharine E. Duckworth
Wake Forest Baptist Health, Comprehensive Cancer Center of Wake Forest University, Winston-Salem, NC, USA

Case Study: *MB is a 55-year-old married female 18 months after autologous HCT for multiple myeloma currently on disability and living at home with her spouse and two high-school age sons. The patient had two kyphoplasty procedures and two cycles of Revlimid, dexamethasone and Velcade in addition to mobilizing therapy prior to HCT. She tolerated transplant well, experiencing mucositis, controlled with pain medication.*

At her initial counseling session, she described physical symptoms including fatigue, neuropathy, back pain, occasional muscle cramping, and profuse sweating up to six times per day similar to a hot flash. Additionally, she reported poor short-term memory, occasional crying spells, and inability to function in her role as a college professor owing to memory deficits, physical limitations, and fatigue. She also worried about the high cost of her maintenance drug therapy that was covered by her husband's insurance policy.

Introduction

Hematopoietic cell transplantation (HCT) is an effective treatment for many life-threatening illnesses such as multiple myeloma, non-Hodgkin lymphoma (NHL), and hematologic malignancies. In this chapter, we define HCT as a group of procedures that involve the collection of stem cells from an individual and their administration to a recipient with a defective bone marrow or immune system caused by a myeloablative preparative regimen. HCT remains a high-risk, intensive, life-prolonging treatment that may be the best option for patients with few alternatives, even when the outcome includes the possibility of significant morbidity. HCT may be associated with a variety of serious biological, psychological, social, and spiritual complications. The above case study illustrates many of the complex and interrelated biopsychosocial issues confronting HCT recipients and their caregivers for months and years post-transplant. We organize potential psychosocial issues facing patients around four thematic stages from the decision to undergo HCT through the trajectory of long-term recovery (Table 32.1) Several studies have identified the temporal trajectory of psychosocial concerns and recovery for HCT recipients [1–3] and many have assessed health-related quality of life (HRQOL) changes over time in this population.

The term "psychosocial" refers to issues that are psychological and social in nature. Our case example depicts a recipient who is unable to return to work following HCT; she encounters both psychologic (e.g. depressive symptoms related to a change in identity from primary bread winner to disabled professor) and social issues (e.g. changes within co-worker network). Table 32.1 lists issues that can become problems over the course of the HCT process. The distinction of when an issue becomes a problem is somewhat arbitrary and largely dependent on the interaction of patient coping skills with the specific issue. For example, if, in our case vignette, the patient had a less demanding work role, perhaps her cognitive deficits would not have led her to apply for disability from her valued position. We focus on the literature identifying psychosocial issues for HCT recipients across the treatment and recovery time period and review the literature on informal caregivers.

Factors influencing psychosocial issues in HCT

Over the past decade, there have been shifts in how the HCT process unfolds for recipients and family members. Below, the forces that continue to shape the HCT process and hence associated psychosocial issues are discussed briefly.

The transplantation of older recipients. The reduced-intensity allogeneic transplantation includes a preparative regimen that is comparatively less toxic than the standard allogeneic transplant. Transplanting older recipients may mean that older loved ones, with less physical strength and stamina, become primary caregivers for a spouse, sibling, parent, or friend.

The collection of peripheral stem cells has nearly replaced bone marrow harvesting. Rather than an operating room procedure with general anesthesia requirements and associated complications of bone marrow harvest, autologous transplant candidates are seen in an apheresis unit after receiving granulocyte colony-stimulating factor. Stem cells are collected over a period of hours on one or more occasions. This change likely reduces the potential anxiety generated by an operating room procedure necessary for bone marrow harvest.

Ready access to information through Internet websites. Information about HCT is readily available to potential recipients with computer access. An ever-increasing database of HCT recipients is tracked through the Center for International Blood and Marrow Transplant Research (CIBMTR) (http://www.cibmtr.org/). Here, any family member or potential recipient can look up detailed information on

Table 32.1 Themes, tasks, and psychosocial issues associated with four stages of HCT

Stage	Issues[a]
I. The decision to undergo HCT	*Theme: active decision-making*
	Confronting mortality and the possibility of death
	Managing the uncertainty of treatment outcome
	Considering alternative treatments
	Financial considerations/insurance limitations
	Psychosocial evaluation
	Informed consent process
	Symptoms of anxiety, depression, and distress
II. Pre-HCT preparation and post-HCT hospitalization	*Theme: aggressive treatment and watchful waiting*
	Adopting the patient role and managing hospital routines
	Managing isolation and acute treatment side effects
	Confronting unfamiliar procedures and treatment
	Separation from family and friends
	Adjusting to altered body image
	Waiting for engraftment
	Heightened physical and emotional vulnerability
	Maintaining morale and hope; managing discouragement
	Dealing with life-threatening complications
	Encountering acute psychological distress
III. Hospital discharge and early recovery	*Theme: transition from intense medical surveillance*
	Managing the loss of daily psychosocial support of medical team and allied healthcare professionals
	Contending with the stress of frequent medical appointments, readmissions, and set-backs
	Reintegration into valued social roles
	Managing unexpected sequelae
	Fear of recurrence
	Adapting to potential frustration, depressive symptoms, and anger
	Complying with self-care guidelines and daily medicine regimen
IV. Long-term recovery	*Theme: establishing the new normal life*
	Re-establishing primary identity/relinquishing patient role
	Recovery of valued roles in community, at work, and at home
	Adjust to losses associated with transplantation
	Return to employment
	Accepting the possibility and reality of long-term effects

[a] Many of these issues continue over the course of the four stages. For example, confronting mortality and the fear of recurrence may be revisited more or less intensely each time the patient returns to the transplant center for ongoing evaluation over many years. Anxiety, depressive symptoms, and distress and also delays in developmental milestones may emerge over the four stages of HCT.

survival statistics and other information. The National Bone Marrow Transplant link (nbmtLINK) (www.nbmtlink.org/) and Blood and Marrow Transplant Information Network (BMTinfonet) (www.bmtinfonet.org) are other rich sources of medical and psychosocial information for recipients and caregivers.

The emphasis on survivorship care planning and post-transplant survivorship monitoring. National and international organizations, e.g. the National Marrow Donor Program, have recommended specific screening and preventive practices for long-term HCT survivors [4]. For cancer survivors in general and HCT recipients in particular, survivorship care plans and the monitoring of clinical outcomes have become the recommended standard of care, even though it has yet to be proven that such monitoring improves outcomes [5,6]. The goal of such efforts is to help patients manage their long-term survivorship. Several important studies of recovery following HCT conducted with relatively large cohorts of recipients and caregivers have identified key problem areas and pointed to potential areas for psychosocial intervention [3,7–9].

The increasing number of unrelated volunteer donors and cord blood products given to recipients without family donors. With the availability of a larger pool of unrelated donors, more prospective recipients can proceed to transplant. Research on the experience of related versus unrelated donors is needed.

Further scrutiny of the costs of transplantation [10]. Financial difficulties are the source of great distress from the early decision-making stage of HCT to long-term survivorship where ongoing medications and lost wages can be extremely costly.

Prominent psychosocial stressors in HCT

HCT recipients and caregivers are confronted with two major sources of psychosocial distress that are more or less prominent throughout the lifespan of the HCT recipient: (1) their disease is life threatening and (2) the treatment itself can be both quality and quantity of life threatening at all stages of treatment, potentially a great source of distress.

Many patients have read or heard from their healthcare provider the prognosis for their particular disease, the fact that it is life threatening. Such an encounter with "mortal time" can debilitate some, invigorate others, and do both at various times along the survival trajectory [11].

A second source of distress for recipients is pre-transplant anxiety about expected emotional and physical side effects of treatment. Acute side effects, such as nausea, mucositis, hair loss, and diarrhea, and long-term effects, including graft-versus-host disease (GVHD) and secondary malignancies, are sources of significant distress. Treatment of many of these side effects requires the use of multiple drugs and therapies with their own side effects ranging from mild discomfort to debilitation. Even when the transplant is medically successful, the ever-present possibility of medical complications can be a source of chronic anxiety.

Stages of HCT and associated psychosocial issues

From early decision-making through long-term survivorship, HCT recipients face a predictable sequence of treatment-related events. We use the term "stage" to refer to a variable period that is characterized by specific tasks and also physical and psychosocial stressors that recipients and their caregivers must manage. In the cancer survivorship literature, the period from diagnosis through long-term survival has been described as the "seasons of survival" [12,13]. In Table 32.1 we identify four relatively distinct stages: (i) the decision to undergo HCT; (ii) pre-HCT preparation and post-HCT hospitalization; (iii) hospital discharge and early recovery; and (iv) long-term survivorship. These stages represent a general map of the HCT process and not an invariant sequence of events and stressors facing all recipients. Some psychosocial issues that appear during one stage of HCT may surface again at a later time. For example, fear of recurrence and what it portends is a significant source of distress for a proportion of HCT patients [14]. However, there is great variability in how patients navigate the HCT process, and few will proceed directly though the stages we describe.

Stage I: the decision to undergo HCT

Deciding to undergo HCT can be very stressful. Most research on decision-making relative to HCT focuses on the provision of written informed consent, a formal stage of decision-making that occurs after the decision to proceed with HCT. Some researchers suggest that the decision to undergo HCT is made prior to formal consent [15]. Furthermore, it is important to realize that in addition to the patient and their loved ones contemplating the life-changing HCT treatment, the medical and psychosocial team is also evaluating candidacy of prospective recipients.

Referral for treatment and selection of candidates

HCT may become a potential treatment option through a formal medical referral, via personal research, or from knowledge gleaned from the treatment experience of acquaintances. Current and comprehensive information is essential at this stage, especially if HCT is seen as the only curative possibility. Patients may be quick to sign on for a curative treatment option and thereby make a rapid psychological commitment to the procedure that is resistant to change [16,17].

The American Society for Blood and Marrow Transplantation (ASBMT) HCT guidelines for clinical centers include a psychiatric/psychosocial assessment as part the general medical workup for all HCT candidates [18]. The assessment is designed to enhance the healthcare team's knowledge of a recipient's psychosocial status, including psychologic distress, psychiatric history, social support, coping style, compliance, and drug abuse tendencies. Information obtained can be used to develop an individualized plan of care over the course of HCT. Standardized approaches to the pre-HCT psychosocial evaluation have been developed that may assist in identifying psychosocial concerns before transplantation and guiding intervention afterwards. Examples include the Transplant Evaluation Rating Scale (TERS) [19] and the Psychosocial Assessment of Candidates for Transplantation Scale (PACT) [20].

Universal psychosocial assessment and selection criteria have not been adopted across transplant centers. However, some researchers have highlighted the prognostic value of psychosocial screening and also the emergence of a high-risk patient profile. Foster et al. administered the PACT to 120 allogeneic transplant patients and identified significant associations between PACT subscale scores and future medical outcomes [21]. Select findings include significant relationships between compliance and reduced inpatient mortality, length of stay and engraftment, drug or alcohol use and engraftment, and receptiveness to education and decreased risk of mortality. Although the overall PACT rating score was not associated significantly with medical outcomes, subscale scores may be good predictors of future outcomes. Several other studies suggest an association between psychosocial status at the time of HCT and important post-HCT outcomes, such as survival [22–25] and risk for medical complications [24,26]. In spite of these findings, considerable uncertainty remains about specific screening variables and the level of risk necessary to rule out HCT candidacy, especially when HCT is the only treatment option [27].

Informed consent

The decision to undergo HCT is formalized in a face-to-face meeting with the transplant physician and the recipient before and/or at the time of pre-HCT hospitalization. At this meeting, the consent form is reviewed in detail (depending on recipient information preferences) and signed, thus becoming a legal document. In theory, the consent process allows patients to make an informed, voluntary decision regarding whether to proceed [28]. In practice, however, this ideal is unlikely to be realized in the HCT setting, for numerous reasons [16,29]. The nature and amount of information required to make an informed decision, the stressful context within which a decision is made, and the reluctance of potential recipients to engage actively in risk consideration all impact the consent process.

The process of obtaining informed consent occurs within a context of considerable distress. Most consent forms contain exhaustive descriptions of medical risks associated with HCT. Researchers have documented that many recipients are considerably distressed in the days prior to HCT [1,30–34]. Distress can compromise the consent process by inhibiting communication with healthcare providers, limiting sensible consideration of risks and benefits, and inhibiting comprehension or memory for information communicated during consent discussions.

Patients may be reticent to engage in discussion of the risks and benefits of HCT [35]. In fact, in the absence of particulars associated with treatment, some patients may enter the consent process with their decision already made. Shannon-Dorcy and Drevdahl reported that a strong desire to avoid death may lead patients to decide to participate in treatment well before they know actual treatment specifics [36]. Discussion of information regarding mortality and morbidity risks has the potential to be threatening, triggering attempts to avoid or minimize important information [37]. Although it may seem maladaptive for patients to distort or avoid information provided in the consent discussion, such avoidance may be critical to the mobilization of the psychological resources necessary to start the arduous, uncertain course of HCT [16]. Prospective candidates may be confronted with other consent and treatment options in addition to information about advanced care planning (ACP) at this juncture.

Advanced Care Planning (ACP)

ACP is particularly relevant for HCT candidates since HCT is an elective procedure that has life-threatening complications and significant mortality rates, and candidates spend time in a consideration phase pre-HCT [38]. Joffe et al. surveyed 155 adult patients pre-HCT and found that 69% reported designating a healthcare proxy, 44% reported completing a living will, and 63% reported discussing life support wishes with personal contacts [38]. Only 39% had formal advance directives (ADs) in their charts and only 16% reported discussing life support wishes with their doctors. ACP was more common in older, college-educated, and allogeneic transplant patients. Ganti et al. [39] found that those most likely to face negative outcomes (death within 1 year) also were those who were less likely to have prepared formally by completing ACP documents. Additional studies should evaluate the nature of this association and should seek modifiable explanatory factors that could be the target of interventions.

ACP has psychosocial implications for patients, loved ones, and formal healthcare providers, as it requires those involved in the process to consider their own mortality and the possibility of becoming incapacitated. The existing psychosocial complications related to chronic disease and pronounced lifestyle changes within transplant recipients are well documented [40]; however, candidates may experience great difficulty anticipating how their lives will change as a consequence of these variables.

Prospective transplant candidates are confronted with the task of making numerous treatment-related decisions at once. Furthermore, decision-making typically occurs in the context of the multiple stressors associated with the HCT setting. Patients and healthcare providers have much to gain from continued research on patient decision-making and optimal methods of informed consent provision.

The case of MB *– The decision to proceed was relatively straightforward and uncomplicated for MB. HCT appeared the best treatment option, and she had excellent social support, financial resources, and job flexibility.*

Stage II: preparative regimen and recovery of marrow function

Preparative regimen

The second stage of HCT begins with the myeloablative preparative regimen consisting of either high-dose or reduced-intensity chemotherapy, often in combination with total body irradiation. The preparative therapy is administered within a 3–10-day period immediately prior to the transplantation of stem cells in either the inpatient or outpatient setting. HCT-related side effects can be severe and vary as a function of the type and intensity of the preparative regimen. Even with noted improvements in supportive care (i.e. antibiotics and infection control procedures), significant and debilitating side effects can continue after preparative therapy has been completed.

When the preparation and recovery phase of HCT is conducted in the inpatient setting, the primary psychosocial issues experienced include adapting to hospitalization and its routines, developing trusting relationships with professional caregivers, loss of privacy, awaiting engraftment, dealing with complications, and physical malaise even in the best of circumstances. Simple hospital routines, such as vital sign monitoring, are essential for management of the painful and potentially demoralizing side effects of preparative therapy. However, the constant intrusions can be a source of significant irritation to patients accustomed to privacy and control of their immediate environment. Pain and nausea typically are managed aggressively through the use of antiemetic and analgesic medications. Cognitive–behavioral therapy (CBT) also can be used as adjunctive therapy for symptom control, especially with patients who are averse to antiemetic and analgesic medications [41,42]. Some evidence suggests that a single-session psychoeducational intervention designed to enhance coping with treatment side effects can be effective in reducing nausea, fatigue, and anxiety in autologous HCT recipients [43].

Some studies have measured distress experienced during this stage II of the HCT process. When psychological distress was assessed in 50 allogeneic and autologous HCT recipients prior to transplantation [34], a significant percentage of recipients reported clinically significant levels of distress (50%) and anxiety (51%). Coordinators underestimated the number of patients with high levels of emotional distress; this suggests a need for periodic, formal assessment of distress in recipients.

Recovery of marrow function

After completion of cytotoxic preparative therapy, new stem cells are infused. While most recipients experience the infusion of stem cells as simple, anxiety is greatly relieved at completion of this central medical HCT procedure. This phase is characterized by physical vulnerability given the recipient's lack of a functioning immune system. During the weeks after HCT, recipients are monitored daily for evidence of stem-cell engraftment and immune system reconstitution. Since many recipients pay close attention to daily laboratory results, both recipients and family members' moods may fluctuate daily depending heavily on the upward or downward movement of their "counts."

Once the side effects of preparative therapy have resolved, and if no serious infectious complications develop, the recipient enters a period of hopeful waiting. Weakness and fatigue are common. Should serious medical complications develop, however, this quiescent state quickly ends. Recipients often react to medical complications with considerable distress. Furthermore, the number and extent of post-HCT medical complications is a good barometer of the length of post-HCT hospitalization required. A prolonged hospitalization can be demoralizing, especially if a tentative discharge date had been set, only to be postponed. At these times, the psychosocial team can play a critical role by helping the recipient to cope with the stresses, disappointments, and lack of control characteristic of this stage.

Additional psychosocial issues during this early period center on the promotion of continued effective coping with the physical and psychological stresses associated with HCT and management of any emergent psychological symptoms. In addition to anxiety and depressive reactions [44], recipients may experience neurocognitive symptoms or neurological complications [45–47]. Episodes of delirium may occur, lasting several hours to several days. Symptoms are diverse and can include alterations in level of consciousness, altered sensory or perceptual function (e.g. hallucinations), impairments in memory, concentration, and higher cognitive processes, mood swings, impaired judgment, and sleep disturbance [48]. Management of these symptoms is challenging owing to their multifactorial etiology.

HCT recipients are more likely to have psychosocial difficulties associated with prolonged hospitalization, including boredom, loss of control and identity, social and physical isolation, and interrupted sleep. These all may be reduced when HCT is an outpatient procedure. However, different problems may develop for outpatient HCT recipients, including perceived lack of immediate availability from the medical team. Research examining the different psychosocial challenges posed by HCT in the outpatient and inpatient settings may be critical to the provision of appropriate support to recipients and families [49].

Despite the presence of multiple and significant stressors during stage II of HCT, there is some relevant research on this time period. Using the M.D. Anderson Symptom Inventory, Anderson et al. studied 100 patients longitudinally in order to determine the severity of symptoms and develop overall symptom profiles in NHL and lymphoma patients [50]. Reported symptom means were mild at baseline, intensified during conditioning, peaked at nadir, and decreased by day 30. The most severe symptoms reported were lack of appetite, fatigue, weakness, feeling sick, disturbed sleep, nausea, and diarrhea. Different diagnoses, conditioning regimens, and performance statuses at HCT presentation make it difficult to predict severity of symptom patterns for individual patients. Nevertheless, this study is a step towards better management when predictable difference can be assumed with different diagnoses.

Garcia et al. compared early quality of life (QOL) outcomes in 105 autologous and allogeneic transplant patients over the course of hospitalization [51]. Despite clinical differences, autologous and allogeneic recipients demonstrated decrements from all subscales at reinfusion relative to baseline and return to near baseline at discharge, with the exception of the functional wellbeing and BMT (symptom) subscale, which indicated worse QOL for patients at discharge. This observation confirms the significant mean effect of time on nearly all QOL subscales seen in other research. The preparatory and hospitalization stage of HCT is taxing physically and emotionally.

Since psychological distress during the HCT hospitalization period is common, periodic monitoring of distress is recommended with short-term counseling and/or psychopharmacologic intervention utilized if needed. There are significant challenges to the accurate assessment of mood and psychosocial status during this stage since recipients' eating and sleep–wake cycles often are disrupted to some extent, and fatigue and lack of energy are common side effects of intensive preparative regimens. A lack of energy also may be the result of anemia, sleep disturbance, and/or nutritional deficits. Persistent fear and worry also can be a significant energy drain. Often, patients mislabel themselves as depressed, especially if they have no prior experience with how an intensive treatment regimen affects mood and outlook. Healthcare providers must consider the variety of underlying explanations for the significantly depressed or fatigued HCT recipient and prescribe the appropriate treatment. When recipients are medically stable, engraftment has occurred, and blood counts are near normal, they are ready for discharge.

***The case of MB** – MB's major problems during stage II were (1) painful mucositis, controlled for the most part with medication, and (2) confinement to one small area of the inpatient setting, described as "… just about the hardest thing I have ever done."*

Stage III: hospital discharge and early recovery

Hospital discharge to home is beginning of the long process of recovery and life reintegration. There are a number of important issues associated with this period, including coping with anxiety generated by leaving the care of the multidisciplinary treatment team, coping with profound physical debilitation, and adjusting to the need to follow strict self-care behaviors, such as avoiding crowds, designed to minimize the risk of infection. Paradoxically, returning home can also be distressing. The possibility of life-threatening difficulties that might emerge when medical assistance is not immediately available can temper excitement about leaving the hospital. Furthermore, frequent clinic follow-up visits can be inconvenient and yet are crucial during early recovery.

Recipients usually leave the hospital physically and psychologically depleted. Rischer et al. studied sleep disturbance and emotional distress during the acute course of HCT [52]. The prevalence of sleep disturbance was 32% before admission, 77% during the hospital stay and 28% after discharge, with difficulty maintaining sleep being the most intense sleep problem during hospitalization. Not unexpectedly, sleep problems were significantly worse during the hospital time relative to other assessment time points. Increased fatigue, decreased physical functioning, and increased treatment-specific distress also were correlated positively with sleep disturbance. The authors concluded that sleep disturbances for HCT patients may be associated more with subjective physical functioning, fatigue, and treatment-specific distress. Furthermore, the significant number of interruptions, and also the frequent need to go to the bathroom, likely contributed heavily to disruption in the overall sleep cycle.

Physical debilitation and concomitant fatigue are a significant challenge for nearly all patients during early recovery, with patients often reporting generalized weakness and fatigue up to 12 months after HCT [1,53,54]. These symptoms can interfere with resumption of routine activities and valued life roles. The anticipated time line for post-HCT recovery varies considerably [55]. Many recipients and family members often are overly optimistic in their expectations, anticipating a quick return to fully functioning, "normal" life. Frustration, depression, and anger can result when these expectations are not met [16]. Family and friends often are puzzled by the tenacity of post-hospital symptoms and may lose patience, perhaps thinking that the recipient is not motivated.

In order to reduce the risk of infection and regain physical strength, recipients are asked to adhere to specific healthcare behaviors. Patients may be required to take several dozen pills each day with varying schedules. Despite the importance of appropriate self-care after HCT, little research has examined this issue. Our experience suggests that adherence to self-care guidelines can be a significant problem after HCT. We have known of one male HCT recipient who acquired a mortal wound infection after shaving with a forbidden straight razor and one patient who contracted a fatal fungal infection after smoking. Although these are notable examples of non-adherence, less flagrant violations of self-care guidelines are common and can result in equally disastrous consequences. In a unique study examining predictors of non-compliance in HCT patients treated in an outpatient setting, Mumby et al. found that 121 patients (80%) were non-compliant with some aspect of their treatment regimen on one or more days of the study period [56]. Depression, psychological distress, and severe nausea and vomiting all were related to increased non-compliance on items such as oral hygiene. There is some indication that screening might identify those at risk for non-adherence with medication regimens [57].

***The case of MB** – The patient's knowledge of her illness, proximity to the transplant center, and supportive social community helped the transition to the new normal begin smoothly. However, fatigue and short-term memory deficits made returning to the classroom quite difficult.*

Stage IV: long-term recovery

Successful recovery after HCT is characterized by adaptation to the residual biopsychosocial and spiritual effects of HCT, diminishment of physical side effects and symptoms, a return to better psychosocial and physical functioning, and resumption of valued life roles. This process usually begins 3–6 months after HCT and can continue for years [55]. There is wide variability in the "trajectory of recovery" following HCT, with some recipients merging back into "normal living" and others never fully recovering, either physically and/or psychosocially.

Support of HCT patients has grown as specific long-term late effects have been identified as affecting an increasingly large number of patients. Jim, in an article with three separate contributions, identified fatigue and lack of energy as significant problems for patients at all stages of the HCT process [58]. However, fatigue can be most distressing during the immediate post-hospitalization stage and long-term survivorship as patients' expectations for returning to normal are not fulfilled. There are multiple mechanisms that contribute to fatigue and reduce physical functioning in HCT patients. These complex biological mechanisms likely account for much of the source of fatigue. Psychosocial distress is likely a reaction to fatigue rather than a causative factor in its etiology. However, both anxiety and depression may contribute to a sense of psychological fatigue. Pharmacologic and behavioral interventions have been developed to address fatigue and the general physical debilitation that occurs.

Syrjala, in the same joint article [58], summarized three aspects of cognitive and psychological health of recipients following HCT: (1) patients are highly resilient, and most will report competent cognitive functioning and emotional stability; (2) during intensive treatment, the majority of recipients will have some decrements in emotional health and also cognitive functioning; (3) approximately 10–40% of all recipients will report long-term neurocognitive and psychological problems. These general statements are highly dependent upon outcome measures used and the subgroups evaluated. Syrjala noted that the pre-HCT assessment can have significant positive and lasting effects in that it establishes a normative baseline for patients talking about their emotions and can normalize future psychosocial distress.

Thygesen et al. conducted a thorough and systematic review of the literature on the impact of HCT on sexuality [59]. A significant number of patients experience long-term sexual problems, including decreased libido and sexual activity, genital alterations, erectile and ejaculatory dysfunctions, and altered sexual /physical appearance. Women reported a greater number of problems than men across all time points and women were less likely to recover from sexual dysfunction. In general, treatment of sexual dysfunction includes education, hormone evaluation, hormonal therapy where indicated, topical or behavioral strategies, and couples interventions. These conditions typically are under-treated in most settings for a variety of reasons, including patients' reluctance to call attention to such a private area of their lives. This is unfortunate since affectionate relating and physical intimacy serve many purposes, including reducing emotional distress, promoting wellbeing, and providing both partners with a sense of vitality.

Physical and psychosocial late effects of HCT

One of the benchmarks used by recipients to gauge the progress of their recovery is the extent to which they perceive they have "returned to normal" [16,60]. Clinical experience and empirical research both suggest that many, if not most, disease-free HCT survivors will experience the sense that they have returned to some version of normal within the first several years following transplant [1,16]. However, the recovery process may take as long as 3–5 years [55]. What is "normal," of course, is dependent upon each recipient's unique perspective.

After the intense experience of HCT, it is common for even disease-free HCT recipients to recognize that their lives "will never be the same." At the same time, paradoxically, many acknowledge that they have "returned to normal," sometimes referred to as a "new normal." Even with the return of what they might consider a normal lifestyle, few recipients are left unchanged by their HCT experiences. Recipients may evidence a variety of late effects, such as neurocognitive deficits, pulmonary problems, sterility, endocrine dysfunction, and weakness/fatigue [61,62]. Even in the absence of such late effects, most recipients experience some interruption in normal developmental tasks (e.g. maintaining a career and establishing satisfactory family relationships).

Despite the presence of physical and psychosocial late effects, the majority of long-term HCT survivors report relatively satisfactory global QOL [63,64]. Broers et al. found that 90% of their HCT recipient sample reported good to excellent QOL 3 years post-HCT despite the fact that about 25% continued to experience significant functional limitations [65]. Recipients often acknowledge having a life of quality while at the same time experiencing significant physical or psychosocial difficulties. This apparent paradox can be explained partially by some evidence that suggests that patients with a chronic disease may alter their perspective on QOL, establishing a lower ceiling of acceptability and redefining what constitutes "good" QOL [66]. This apparent "response shift," where internal ratings of what constitutes a life of quality can change over the long course of treatment [67]. also might be explained by the potential of the transplant experience to exert a positive impact upon recipients' lives. As in any life-changing event, the long-term impact of HCT may not be uniformly negative. Recipients often experience positive psychosocial sequelae of their transplant experience [68,69].

Bishop summarized findings regarding psychosocial sequelae of both HCT recipients and caregivers at least 1 year post-HCT [70]. She surmised that psychosocial recovery can take longer than physical recovery and, like Mosher et al. [64], named specific long-term psychosocial issues that have been identified by patients as problematic, including distress, depression, anxiety, post-traumatic stress disorder, sexual problems, and cognitive difficulties. She concluded that (1) addressing psychosocial sequelae is important since these issues, especially elevated distress and depression levels, can predict adherence and poorer return of function; and (2) early identification and referral for treatment of psychosocial problems could result in positive outcomes, including better satisfaction with care, improved doctor–patient communication, and fewer complications.

Neurocognitive deficits

Neurocognitive deficits following HCT pose a significant psychosocial stressor for many patients, depending upon the extent of the deficit and how it impairs daily functioning. We saw in the case of MB that memory difficulties resulted in an inability to function as a college professor. Syrjala et al. studied the trajectory and extent of long-term cognitive dysfunction from 1 to 5 years after treatment in 66 allogeneic HCT recipients and matched controls who completed standardized neuropsychological tests [62]. HCT recipients recovered significant cognitive function from the 80-day assessment to 5 years on all tests except verbal recall. Between 1 and 5 years, both verbal fluency and executive function improved but motor dexterity did not, remaining below controls and more than half a standard deviation below population norms. On the global deficit score, 41.5% of survivors and 19.7% of controls had mild or greater deficits.

Survivorship following HCT

Survivorship programs and care plans in general [71], and those specifically designed for HCT recipients [72], have been described as the number of survivors has increased and the recognition of late effects grows. Survivorship programs have gained increasing legitimacy with the proposal to have a specific written or digitized medical history of the patient and recommended health maintenance and surveillance appointments. The survivorship care plan document has been applauded universally and yet evidence to support its influence on outcomes is sparse in the general cancer population [5,6] and non-existent in the HCT literature. Nevertheless, a logical, rational argument can be made for the effectiveness of such information to empower patients to seek the best care possible following such an intensive treatment regimen as HCT.

After reviewing 22 prospective studies, Mosher et al. reported on physical, psychological, and social sequelae following HCT [64]. They found that a significant proportion of HCT recipients experienced persistent anxiety and depressive symptoms in addition to fatigue, sexual dysfunction, and fertility concerns over the long term. Nevertheless, the majority of HCT survivors resumed work, school, or valued household roles. The HCT recipient's life-threatening disease and transplantation can be conceptualized as a psychosocial transition, defined as a major life experience that requires individuals to restructure ways of looking at the world and plans for living in it. As noted earlier, these transitions can present recipients with a paradoxical combination of personal growth *and* deficits in physical, social, and emotional wellbeing. Such a paradox is consistent with the psychosocial transition paradigm offered by Mosher et al..

Long-term QOL and symptoms

Grulke et al. reviewed literature that included a total of 2804 HCT recipients [73]. This comparatively large sample size yields important information. QOL was lowest during inpatient hospitalization. Patients returned to pre-transplant QOL levels at approximately 1 year, yet fatigue, dyspnea, and insomnia remained elevated. The authors concluded that group data may provide general guidelines for patients; however, they cautioned that it is impossible to know for how many patients these predictions will hold true. A host of moderating factors impacts the pace at which QOL returns.

Recognition of psychosocial late effects is achieved best through routine and periodic monitoring. The CIBMTR, the European Group for Blood and Marrow Transplantation and the ASBMT developed screening guidelines for long-term HCT survivors [74]. These guidelines recommend that a mental health provider conduct a psychosocial assessment at 6 and 12 months and annually thereafter, assessing the following: depressive symptoms, psychological distress, sexual functioning, dietary and exercise habits, substance abuse, family functioning, and the adjustment of the primary caregiver. In addition to their impact upon general physical health, certain health behaviors may be linked to the experience of distress and hence may be useful indicators of psychosocial difficulties.

Physical activity and exercise

There is a growing body of research examining the impact of physical activity and exercise interventions on functional and psychosocial outcomes. In some of the earlier studies on structured programs of physical activity, participation by HCT survivors has been associated with better QOL, less distress, and less fatigue [75–78]. Almost all HCT recipients undergo significant physical debilitation due to intensity of the treatment, length of hospital stay, and reduced physical activity, and impairment of daily sleep and eating patterns. Wiskemann and Huber reviewed 15 studies and concluded that physical exercise could be a potentially promising intervention to ameliorate many of these side effects [79]. The most common interventions were isolated aerobic activity during and after HCT. They proposed that physical exercise interventions could affect endurance and strength performance, psychosocial parameters, body composition, and immune system/functions and concluded that there is a need for randomized controlled trials (RCTs) with larger sample sizes. Additional studies indicate that exercise could have a beneficial effect on side effects and HRQOL both during and after HCT [80–83]. One study improved on previous research by studying the effects of a partially self-administrated exercise program [83]. Investigators conducted an RCT where allogeneic patients were placed in either an exercise or social contact control group. Training was conducted in a home-based setting before hospital admission, during inpatient treatment, and during a 6–8-week period after discharge. All exercise participants were asked to participate in three endurance and two resistance training sessions per week, including warm-up and cool-down periods of aerobic activity. Every effort was made to standardize the exercise intervention, particularly during the inpatient stay, and to provide some guidance both prior to and after HCT. The exercise group showed improvements in fatigue, physical fitness functioning, and ratings of global distress.

The Wiskemann study, like others noted, indicates that early and structured physical rehabilitation programs can make a difference for a significant percentage of HCT recipients. The extent to which prior exercise behavior and other factors influence patients' motivation for these programs is unknown. Somerfield and Rizzo [84] called for a large multicenter trial powered sufficiently to answer the question of whether exercise programs in the early period after transplantation can improve both physical functioning and QOL. Questions remain as to whether exercise program benefits endure beyond the initial short-term effects. In the absence of a more elaborate multicenter RCT, the authors concluded that there is enough evidence to support structured exercise programs for HCT participants and that transplant centers could introduce simple, structured, and low-impact exercise programs into clinical practice.

Long-term recovery from HCT is characterized by gradual passage through a series of psychosocial transitions [64,85] dictated by the changing physical and psychosocial concerns of primary importance to the HCT recipient [1,2]. Early in the course of post-HCT recovery, recipients likely are concerned most with surviving and achieving a measure of medical stability. As months and even years pass, recipients focus more on psychosocial issues revolving around sexuality, occupational adjustment, social relationships, fear of recurrence, and coping with physical limitations. Ultimately, most surviving recipients achieve a level of psychosocial equilibrium and move on with their lives [85].

The case of MB *– 18 months after HCT, MB learned to accept her new normal, which included chronic pain, reduced stamina, and low energy relative to her pre-HCT state, permanent disability due to cognitive changes, and the high cost of maintenance medication. Yet, her depressive symptoms responded to counseling and her general outlook on life improved.*

Psychosocial Issues in HCT: informal caregivers

Informal caregivers are the family members, friends, and acquaintances who often serve as an "essential extension" of the family and healthcare team [86]. Throughout the transplant and recovery processes, they can offer emotional and logistical support and motivation, and help with daily tasks of living and even the provision of medical assistance. At the same time, most caregivers continue to balance other life roles, such as parenting or elderly care, work, and home management. The informal caregiving role may extend for a significant length of time post-transplant and even change the very nature of the caregiver–HCT recipient relationship [87]. Some preliminary data suggest that the presence of a caregiver during HCT hospitalization is linked to better survival during the first year post-HCT for recipients [88]. Even if supportive caregiving does not influence quantity of survival, it certainly affects its quality. This section highlights current research on these unsung heroes.

There are several important developments in the literature on HCT caregivers. Researchers have tried to identify the specific needs of HCT caregivers, document the nature and consequences of the burden they experience over time, perform interventions to ease burden, and examine caregivers in inpatient versus outpatient settings.

Beattie and Lebel investigated the emotional impact and high distress reported by caregivers [89]. It is not surprising that distress among caregivers was highest prior to transplant and decreased over time, since the informal caregiver is exposed to many of the same psychosocial stressors as recipients themselves. The vicarious experience of watching a loved one suffer can be profoundly difficult. Wulff-Burchfield et al. highlighted numerous caregiver issues that may persist long after the transplant process, including psychological symptoms (e.g. anxiety and depression), physical symptoms (e.g. fatigue and weight loss), and persistent familial, marital and social structure changes [86]. Typically, the bulk of the care and support are centered on the HCT recipient. Unlike the HCT recipient, however, caregivers usually are not permitted to assume the "sick role" that permits dependence upon others for daily assistance. On the contrary, caregivers often experience the imposition of increased expectations by the HCT recipient and professional health team.

Caregivers report distress levels that are equivalent to or even higher than those reported by patients [89]. Variables associated with distress include female sex, higher patient distress levels, and higher perceived levels of burden. Caregivers reported fears related to the future, uncertainty, the need to balance personal needs with those of their loved ones, and difficulty with role transitions. Alongside these concerns were positive aspects of being a caregiver, including personal growth and positive relational changes. In a study of 56 caregiver and allogeneic transplant recipient dyads, caregivers reported the most difficulty relative to tending to the emotional health of their loved ones as well as talking about the future and the possibility of death [90]. As strain increased in any life domain, QOL correspondingly decreased. QOL also was related positively to predictability in their caregiving, highlighting the importance of caregiver preparedness, clear information provision, and predictability, when possible. Similarly, in a study of 58 caregivers, the most common needs were those related to information, particularly regarding home care after discharge and diagnosis, fear, and leisure activity deficits [91]. Together, these results highlight the high distress levels experienced by caregivers alongside positive aspects of this active process.

Comparison of the HCT caregiver with healthy controls or normative data also places the status of the HCT caregiver in context. Langer et al. studied 131 spouse caregiver–recipient dyads from pre-transplant through 24 months post-HCT and incorporated norm data from a sample of healthy controls [92]. While negative affect declined over time among both caregivers and recipients, caregivers reported more depression and anxiety relative to recipients and controls. Although similar levels were reported pre-transplant, caregivers reported lower levels of marital satisfaction relative to the recipient at 6 and 12 months post-transplant. Similarly, Bishop et al. compared current HRQOL and post-traumatic growth in 177 spouse/partner caregivers and HCT recipient [roughly 2–19 years post-transplant (mean = 6.7 years)] dyads and 133 recipient-matched, healthy controls [7]. Caregivers and healthy controls reported better physical health than HCT recipients. However, both partners and recipients reported more depressive symptoms and sleep and sexual problems than controls. Caregivers reported less social support, dyadic satisfaction, and spiritual wellbeing and more loneliness than *both* recipients and healthy controls. Furthermore, caregivers reported less post-traumatic growth than recipients. While reporting better physical health status, caregivers reported equal or significantly worse psychological and social status relative to HCT recipients.

Demonstrating the possibilities in interventional work, Langer et al. developed an RCT based on an expressive talking paradigm for the partners of HCT survivors, measuring physiologic, subjective, and expressive variables related to disclosure of their deepest feelings about their partners' transplant experiences [93]. Relative to controls, participants endorsed more negative emotion and more negative emotion words, and believed that the exercises were more meaningful and useful, suggestive of more emotional processing. Even though participants rated the emotional expression exercise more "emotionally effortful," they also described it as meaning-laden and helpful.

The trend towards the provision of HCT care in an outpatient, ambulatory setting has led to a need to identify how this movement affects caregivers [94]. For outpatient models of HCT care delivery to be successful, the presence of a suitable caregiver is essential. Caregiver outcomes therefore must be important considerations in the evaluation of care delivery settings. From pre-transplant to 12 months post-transplant, Grimm et al. compared the emotional responses and needs of 26 HCT caregivers from an inpatient setting with 17 caregivers from an inpatient/outpatient setting [95]. Few differences were found in caregiver distress between the settings, yet some evidence suggested that the inpatient/outpatient setting might be associated with less caregiver mood disturbance. Given the small sample size and the lack of random assignment to setting, the results warrant replication.

In summary, informal caregivers are essential team players for recipients and the healthcare team. The available research suggests that the caregiving experience in the HCT setting can be physically, emotionally, socially, and financially stressful. Examining caregiver outcomes based on inpatient or outpatient setting will continue to be important as the most efficient models of care delivery are developed. Additional studies are needed on the unique needs of homogeneous caregiver groups (e.g. spouse vs. friends), both the intrapersonal and interpersonal (i.e. dyadic) experience of caregiving, changing needs over time, and the incorporation of theoretical frameworks into caregiver research [89].

Conclusion

HCT is an intense treatment procedure that can extend over many weeks, with side effects lasting months to years after the initial conditioning and recovery period. It is utilized for patients who differ by disease site, age, gender, performance status, amount of previous chemotherapy, and coping and supportive resources. Hence broad generalizations about the experience of recipients and caregivers have limited utility. Nevertheless, the basic experience is similar for nearly all HCT recipients over the trajectory of care beginning with decision-making and culminating in long-term survivorship. Even with continual improvement in medical treatment regimens and supportive care, HCT remains a life-threatening treatment for life-threatening diseases that can produce a range of serious physical and psychosocial morbidities including ongoing fear of cancer recurrence [96,97]. We have summarized the important psychosocial issues that arise over the course of transplantation. There is a pressing need to develop simple interventions to help recipients and their caregivers adapt to the ongoing challenge of survivorship across the trajectory of treatment and recovery over the course of a lifetime.

CHAPTER 33

Assessment of Quality of Life in Hematopoietic Cell Transplantation Recipients

Karen L. Syrjala[1] **and Samantha Burns Artherholt**[2]

[1] Fred Hutchinson Cancer Research Center and University of Washington School of Medicine, Seattle, WA, USA
[2] University of Washington School of Medicine, Seattle, WA, USA

Introduction

Health-related quality of life (QOL) has been well-described in myeloablative hematopoietic cell transplantation (HCT) patients from pre-transplant through at least 10 years after transplantation [1–7]. As a result, much is known about QOL outcomes over time for myeloablative autologous and allogeneic sibling and unrelated transplant recipients within and across many diagnoses. The central consistent findings of these studies are that (1) physical function returns to pre-transplant level for a majority of survivors by 1 year, (2) by 3 years, 75–90% of survivors are back to full-time work, and (3) the majority of patients navigate the challenges of HCT with good psychological health. Although the QOL outcomes of non-myeloablative HCT recipients have been less well described, research indicates that symptoms and overall QOL during acute treatment is poorer for those receiving myeloablative versus non-myeloablative or reduced-intensity treatment [8,9], whereas QOL is comparable in the long term for those who are disease free after either transplant type [7,10]. Notwithstanding these generally positive outcomes, a majority of patients will have residual problems in specific domains of QOL such as fatigue, sexuality, fertility, and musculoskeletal symptoms. Other transplantation QOL outcome comparisons are not as clear, such as comparison of umbilical cord blood with other types of HCT outcomes, long-term QOL after HCT for multiple myeloma, or non-malignant diseases other than anemias.

Excellent measures and methods for evaluating QOL have been validated with HCT patients. Population-normed instruments are available for comparison with HCT-related outcomes. Computer-adapted online assessments are validated that facilitate routine, rapid assessment and provide immediately accessible results, enhancing the potential utility of QOL assessments for clinical care.

Progress has been made in previously under-considered groups affected by HCT. Research has described pediatric outcomes, caregiver impacts, and QOL in patients living with chronic graft-versus-host disease (cGVHD). Despite progress, a dearth of research remains in two areas: clinical trials to improve QOL outcomes, and QOL outcomes research following relapse after HCT. In addition, research is lacking in documenting outcomes for bereaved families of patients who die.

This chapter summarizes what is known about QOL during and after HCT, and considers assessment issues necessary to understand when interpreting results or doing research that includes QOL outcomes. Other chapters discuss the application of QOL within outcomes research, in the psychosocial domain, and with sexual problems (see Chapters 28, 32, and 34).

Definition of health-related QOL

Most QOL researchers would concur that QOL refers to “the extent to which one’s usual or expected physical, emotional, and social wellbeing are affected by a medical condition or its treatment” [11]. Elements essential in any definition of QOL are *multidimensionality* and the *patient’s perspective*. With time, QOL has grown to encompass not only subjective evaluation, but also those behaviors that may be reported by patients but go beyond subjective experience to include functional impact in addition to activity reports. Whereas medical outcome studies often define outcomes in terms of peak toxicity or time to an event such as relapse or death, QOL is usually described in relation to non-transplant controls or as a change from pre-transplant status. A central tenet is that QOL is *relative* to the current situation and the *expectations* of patients within the circumstances in which they find themselves. As an example, patients with major toxicities during transplant can report good psychosocial QOL and satisfaction with QOL because they believe they are doing as well as possible in a difficult situation, and they have the support they need from people important to them [5]. Despite this subjectivity, QOL correlates with medical, functional, and observational outcomes including both severity of cGVHD and comorbidities [12–15]. However, clinician ratings and toxicity scoring do not substitute for patient reports in evaluating changes in QOL during and after HCT [16].

An important element in QOL outcomes research is the concept of patient-reported outcome (PRO). This concept has been instituted by the US Food and Drug Administration (FDA) for medical product development and labeling [17]. PRO measures include reports of disease symptoms, treatment of adverse effects, functional status, or overall wellbeing [18]. A useful guideline for determining appropriateness of a PRO is offered by Lipscomb et al.: “the concept measured by the PRO instrument should be relevant and specific to the population, condition, and treatment to yield clinically valid and useful information” [19]. This definition is somewhat narrower than that of QOL and linked more explicitly to medical outcomes. However, the term “PRO” is being broadly accepted as covering aspects of health status evaluation that come directly from those individuals being evaluated, without modification or interpretation by another observer. It seems likely that, over time, PRO will replace QOL as a broad term and end-point of clinical trials, given its

importance to medical treatment and potentially to reimbursement decisions. Indeed, PRO data may even be more useful as a clinical trial end-point than conventional toxicity information in some cases [20]. However, components of QOL not directly linked to medical decision-making, such as spirituality or social function outcomes, impact on caregivers, and return to work, will always be of interest to patients and families preparing for treatment, recovery, and long-term survival needs.

Dimensions of QOL

Concepts of QOL continue to adhere broadly to a three-level "pyramid" first described by Spilker [21]. He tops the pyramid with global assessment of wellbeing. The middle level includes multidimensional assessment of the physical, psychological, economic, spiritual, and social domains. The base details subcomponents of each domain; for example, work and symptoms are aspects of the physical domain. Other subcomponents include social and recreational activities, sexual function, relationships with the medical team, religion, perspective on life, personal control, and components of health and treatment that contribute to stress or worry for the patient. Ferrell et al. [22] interviewed 119 adult bone marrow transplant survivors at least 100 days post-transplant to determine what QOL meant to these patients. They categorized the many positives and negatives noted by survivors into themes and then into four domains matching those of Spilker: physical, psychological, social and spiritual/existential wellbeing. Consistent with these definitions, the multidimensional QOL measures used in most HCT studies include physical, mental, and social function domains, in some cases with the addition of items specifically relevant to HCT symptoms and other areas of interest (Figure 33.1).

Smith et al. found that patients perceived their health status and QOL as distinct from each other [23]. Physical function weighed more heavily in assessments of health status, whereas emotional health weighed more heavily in judgments of QOL. Social function was not prominently considered in either global rating. Consistent with this emphasis on health outcomes, medical studies incorporating a QOL assessment have successfully used the shortened version of the Functional Assessment of Cancer Therapy – BMT Module (FACT-BMT) with only the physical wellbeing, functional wellbeing, and transplant-specific items. This abbreviated measure, called the Trial Outcome Index, is useful in studies when targeted outcomes are focused on physical function and symptoms [24,25].

Researchers have documented resilience as they recognize that most patients with cancer and those receiving HCT do very well in the psychological domain. Four concepts examined are spirituality, optimism, benefit finding and "post-traumatic growth." In essence, the ability to find positive meaning beyond the diagnosis and to perceive gains in addition to losses in the disease and transplant process predict better long-term adaptation [4,26–28]. Most often gains are reported as greater appreciation for life, closer interpersonal relationships, reprioritizing "what really matters," feeling closer to God, inner strength, and a sense of peace and thankfulness [4,22,29,30]. Although these concepts do not appear in most health-related QOL measurements, they are usually noted as important outcomes by patients, clinicians, and researchers examining qualitative outcomes of HCT [31,32].

In summary, QOL is always evaluated from the patient's perspective. It is rated in part by internal comparisons with how much worse things could be. Thus, patients with poor physical health may report good psychological or overall QOL. Increasingly, studies are measuring optimism, benefit finding, spirituality, and resilience as

outcomes that may predict both mental health and medical outcomes. Although many dimensions of QOL can be considered for evaluation, physical and mental components are nearly always included.

Phases of HCT and related risk factors for QOL outcomes

Transplantation is a dynamic and individual experience. While consistent patterns can be described, a patient will have his or her own trajectory of illness and recovery depending on both medical and psychosocial factors. Research has more recently been examining QOL changes over time based on different treatment types, complications such as cGVHD, and baseline QOL domains [1,16,33–36]. Although 60–80% of transplant survivors return to pre-transplant levels of function and QOL by 6 months to 5 years post-transplant, research consistently finds that survivors' average overall QOL and function within specific domains remain lower than for age-matched population norms [35]. The majority of this dysfunction seems to result from clinically meaningful impairments in 20–33% of survivors.

There are two methodologic concerns in past research that contribute some instability to QOL results across studies. One is that much of the research is cross-sectional, clustering patients with widely varying times since transplant and diverse diseases or treatments. Another is the range of assessment instruments used to evaluate QOL outcomes, which prevents ready comparison across studies. Nonetheless, outcomes are more similar than different, lending confidence to the robustness of QOL results.

Pre-transplant

Patients arrive at transplant with diverse diseases, histories of treatment, levels of physical function, and psychosocial, informational, and financial resources. The conclusion from numerous studies is that pre-transplant physical condition and psychological status predict later physical and psychologic adaptation in addition to survival [1,35,37,38]. Psychosocial predictors of outcome have received substantial attention, although data indicate that pretreatment physical QOL not surprisingly also predicts transplant outcomes [1,5,35,39]. Emotional distress predicts acute transplant symptom course, especially for pain and distress [6,40,41]. Psychosocial needs are greatest just prior to transplant if judged by the percentage of patients with clinically significant anxiety or depression at different phases of treatment and recovery and their improvement after HCT [1,5,34]. These replicated findings support guidelines calling for routine assessments of distress and psychosocial function [42,43].

Acute treatment

During the immediate post-transplant weeks, assessments find that survival is the axis around which other aspects of QOL are evaluated. In consequence, patients attribute their experiences to physical rather than psychological causes during this phase [5]. Patient focus is dominated by mouth pain, nausea, fatigue, hair loss, infection risks, adhering to treatment requirements, and efforts to maintain self-care. Research supports lower toxicity, with fewer symptoms, during acute treatment for those receiving reduced-intensity conditioning [44,45]. As would be expected, patients with acute graft-versus-host disease (GVHD) have measurable declines in QOL compared with those not experiencing acute GVHD [9,24,35,39]. A recent evaluation of QOL in the first 100 days post-transplant indicated that symptom severity during this period is significantly correlated with QOL [8]. As hospitalization has shortened and treatments for acute toxicities have improved, investigations have increasingly moved from a focus on acute QOL to recovery and long-term outcomes.

Recovery

Physical and overall QOL return to pre-transplant QOL on average in 6 months to 1 year after HCT [1,34,35]. Although data are mixed on the recovery course for allogeneic compared with autologous transplant recipients in the year after HCT, with some finding that autologous recipients have better QOL in all domains to the first year after transplant compared with allogeneic transplant recipients [8,46], others have found that any discrepancy in QOL based on transplant type disappears by 1–2 years post-transplant [1,3]. Different aspects of psychological recovery occur at different time points. Whereas depression and clinical anxiety recover on average by 1 year after HCT, distress and emotional adjustment to the impact of diagnosis and treatment can be a longer process for many survivors, taking 2–5 years, in part depending on long-term complications such as cGVHD [1,35]. Since populations receiving reduced-intensity conditioning have generally not been eligible for high-dose conditioning, it is difficult to compare QOL and function across the two groups. Nonetheless, one prospective study compared the QOL of patients receiving reduced-intensity conditioning and myeloablative HCT, and found that both groups returned to baseline QOL by 2 years after transplantation [47].

Multiple studies have reported that the following risk factors predict a slower or poorer return of function: physical health pre-transplant, depression, psychological distress, lack of social support, female sex, myeloablative conditioning, specific diagnoses, decline in body mass index, and medical complications during treatment and recovery, in particular cGVHD [1,5,6,39,48]. Older adults have more difficulties with medical recovery from high-dose treatment and are less likely to return to work or social activities; however, they have better social function after HCT [3,6,34,35,39,49]. Risk of cGVHD or other medical sequelae increases with age, and active treatment for complications is associated with poorer QOL. Overall, while medical risks vary significantly with age, QOL is noteworthy for a lack of major differences based on age independent of the higher medical risks that accompany age.

Although survivors have slower recovery in the years following transplantation if they struggle with cGVHD, or have pulmonary disease, immune compromise, or other medical complications [6,49–53], once these medical complications resolve, QOL generally improves to levels equivalent to those of patients who never had them [3,9,24,52]. Similarly, patients receiving allogeneic transplants may have more physical and emotional difficulties in the first year, but by 12 months, physical and psychological difficulties do not differ between types of transplant [1,3].

Return to work justifiably receives a good deal of attention in recovery and long-term function reports. Although 30–60% of survivors begin to return to work by the end of their first year post-transplant, return to full-time work continues to occur for patients into the third year [1,54,55]. Fortunately, by 3 years post-transplant, studies agree that 80–90% of survivors have returned to full-time work or school [1,6,55–59]. Interestingly, although the pace is slower, overall rates of return to work for HCT recipients are similar to those in patients with other cancers [59]. It appears that rates of return to work may differ to some extent by the country in which a patient lives, perhaps as a result of the different economic incentives or rehabilitation programs available [60,61].

Long-term function and late effects

Longitudinal and cross-sectional studies find that, by 5 years, a large majority of adult survivors of HCT are functioning well in their return to "normal" life in the domains of physical, psychological, social, existential, and overall subjective QOL [2,4,7,34,35,39,57,62]. However, specific deficits remain at rates higher than those of the general population. Long-term survivors report more accumulated health problems, fatigue, musculoskeletal dysfunction, more limitations in sexuality and social function, and greater infertility concern than case-matched controls [2,4,9,46,58,63–66]. Persisting cGVHD continues as the major predictor of poorer overall health and QOL [35,39,53]. Otherwise, these recent reviews conclude that strong evidence supports poorer long-term outcomes for those with worse physical functioning, emotional distress, depression, or lower social support before HCT. Women consistently report poorer psychological outcomes on average and are less likely to return to work.

Studies of adults indicate that 20–56% enter transplant with cognitive deficits that could interfere with function [67,68]. Longitudinal research has reported neurocognitive deficits up to 5 years after HCT in about 40% of allogeneic survivors compared with about 20% of non-transplanted case-matched adults, although most deficits are in the mild range [69–71]. A recent meta-analysis found no sustained changes from before to after HCT in survivors [72]. Although no single risk factor consistently predicts sustained neurocognitive deficits, cumulative risks do seem to result in poorer cognitive function [73].

Results are inconsistent in terms of whether long-term survivors have higher rates of psychological dysfunction than normative rates for the general population, although studies agree that 67–85% do well [2,4,35,39]. Survivors do report other problems, including infertility concerns, especially if they are childless, more difficulty obtaining life and health insurance coverage (although actual rates of coverage are comparable to rates in control groups), and long term financial concerns [2,57,74]. Longitudinal studies beyond 10 years are needed to determine whether aspects of QOL decrease more rapidly over time in HCT survivors relative to a naturally aging population since survivors remain vulnerable to late medical complications and mortality risks.

In summary, the physiological and psychological phases, impacts, and risk factors after HCT have been well defined. Common problems post-transplant include fatigue, musculoskeletal complications, cognitive difficulties, sexual dysfunction, infertility concerns, and efforts to manage continuing uncertainty and fear.

Pediatric QOL

Approximately 30% of children have elevated distress before and during treatment, with declining distress in the 6–12 months following HCT [75–77]. Risk factors for high levels of distress and low QOL in childhood survivors include receiving a transplant from an unrelated donor, increasing age, lower socioeconomic status, and Asian race, with African American children reporting higher QOL [78–80]. By 1 year post-transplant, both mothers and children report good QOL [76,79], and most long-term survivors lead independent, productive lives in adulthood although not without complications [81–83]. Sanders et al. found that physical functioning was poorer both for those with myeloid diseases and females, with depression more common in females, consistent with adult findings [83]. In short, research testifies to the resilience of children not unlike the resilience of adults, but not without psychological distress, need for social adaptation, cognitive limitations, and other long-term complications in a substantial minority. The restriction to overall positive outcomes is that it has not been possible yet to track many pediatric survivors past their twenties since cohorts of mature adult survivors of pediatric HCT remain small in number.

Caregivers and parents of transplant recipients

As central a role as families play both during and after HCT, research on family caregivers is only recently making headway in evaluating their QOL needs. Whether before, during treatment, or long term after HCT, QOL in caregivers is low compared with norms and their patient counterparts [84–88]. The stressful impact of supporting a loved one through HCT can last years beyond the active caregiving phase, with caregivers retaining recollection of more negative changes than survivors [84,89].

Parents of pediatric HCT patients report significant distress in the course of their child's treatment. Although some studies report that mothers of pediatric HCT patients suffer the greatest trauma in the course of their child's treatment [90], other researchers find that mothers and fathers both report significant distress symptoms [91,92]. Younger mothers and those experiencing more depression or anxiety at the time of HCT are more likely to continue to be distressed 18 months later [90]. Other caregivers manage remarkably well from early evidence, despite their levels of acute distress. Further research is needed on QOL assessment of caregivers of HCT patients, both during and after transplant.

QOL measurement

Table 33.1 lists measures commonly used to assess QOL components in HCT. Although QOL data can be rich and informative, inadequate appreciation of data collection requirements necessary for high-quality data and the importance of minimizing non-random missing data have limited the clinical value of many early QOL studies. As important as selecting the appropriate measure is the need to plan the approach to patients, retention for follow-up to maintain high response rates, quality control procedures to assure all items are completed unless intentionally skipped, and the statistical methods to account adequately for missing data whether through imputation or inclusion of unconditional analyses. When presenting results in studies with high rates of attrition through mortality or other non-random causes, it may be necessary to provide both conditional and unconditional results, i.e. report the probability of a surviving patient indicating a positive outcome (conditional analysis, often a high proportion as described in the review above) and the probability of a patient surviving *and* indicating a good outcome (unconditional analysis, which may be a much lower proportion) [93]. Wong et al., using pattern mixture modeling to represent those lost through various causes, demonstrated the increased likelihood that those with poorer QOL outcomes will be missing in conditional analyses [34]. Chapters 27 and 28 provide more information on considerations and methods in analyses of QOL outcomes.

In selecting measures of QOL in HCT recipients, the ideal is to use measures with established norms, reliability, and validity in HCT cohorts. In addition, the availability of broader population norms is valuable to permit a comparison of HCT results with those of other groups. However, the use of generic measures tested across broad populations also has a downside. There is an inherent trade-off in benefits of generic versus specific QOL measures. HCT-specific measures such as for cGVHD effects may be more sensitive, specific, and

Table 33.1 Selected QOL measures used in HCT

Relevant measures tested in HCT[a]	HCT specific	No. of items	Scores
Multidimensional QOL			
EORTC-QLQ-C30 (European Organization for Research and Treatment of Cancer Quality of Life Questionnaire – C30)	Yes	30	9 subscales, no total score
EORTC QLQ-HDC29, HCT Module		29	HCT module score
FACT-BMT (Functional Assessment of Cancer Therapy – BMT)	Yes	27 + 18	5 subscales, BMT module score, overall score
Trial Outcome Index (TOI)		37	(TOI includes 3 subscales)
SF-36 (Short Form 36 Health Survey)	No	36	8 subscales plus physical and mental components, no total score
EQ-5D	No	5 + 1	Summary index and visual analog scale health state item
PedsQL (Pediatric Quality of Life Inventory)	Yes	23	4 subscales, total score and physical summary, psychosocial summary
Transplant Module			
Versions for 3 age groups and parents		46	8 subscales
Child Health Ratings Inventories (CHRIs)	Yes	38	4 subscales, overall score,
HSCT Disease-Specific Impairment Inventory		23	HSCT inventory
Versions for 3 age groups and parents			
Symptoms			
M.D. Anderson Symptom Inventory (MDASI)-BMT	Yes	23	2 subscales, total score
Rotterdam Symptom Checklist (RSCL)	No	38	3 subscales, global score
Muscle and Joint Measure (MJM)	Yes	4–33	4 subscales, total score 4 screening items
Brief Pain Inventory (BPI)	No	10	2 subscales, severity, interference, no total
Brief Fatigue Inventory (BFI)	No	9	Total score
Fatigue Symptom Inventory (FSI)	No	14	2 subscales, total score
Pittsburgh Sleep Quality Index (PSQI)	No	18	7 subscales, global score
Mental health, emotional wellbeing			
BSI (Brief Symptom Inventory – Short Form)	No	18	3 dimensions, global severity
CESD (Center for Epidemiologic Studies – Depression)	No	20	Total score
CTXD (Cancer and Treatment Distress)	Yes	22	6 subscales, total score
HADS (Hospital Anxiety and Depression Scale)	No	14	2 scores
PHQ-9 (Patient Health Questionnaire-9, Depression Scale)	No	2–9	Total score, 2 screening items
Coping style			
Brief COPE (Coping Orientations to Problems Experienced Scale)	No	28	14 subscales in 3 groups; can select from subscales
Social function			
MOS Social Support Survey (Medical Outcomes Study)	No	19	4 Subscales, overall index
Spiritual, existential wellbeing			
FACIT-SP (Functional Assessment of Chronic Illness Therapy – Spirituality and Wellbeing Scale)	No	12	Total score
Sexuality			
SFQ (Sexual Function Questionnaire)	Yes	40	9 subscales, overall score, medical impact score

[a] Updated measure information is available from websites for the measures listed by searching for the measure name.

informative but are then only relevant to HCT-specific problems and cannot be compared with other cancer or general population norms.

In QOL measurement, a "response shift" is expected as patients' conditions change medically. Patients naturally reprioritize concerns, and self-report is, by human nature, relative to expectation rather than being tied to medical status. In the transplant process, health may decline, but many patients still report good psychological function [5,94]. Another factor that can shift response is the changing relevance of assessment dimensions. While physical symptoms may be the central focus during acute treatment, focus shifts in long-term follow-up to functional abilities and emotional adaptation [33]. This is a major reason why excellent measures in one circumstance may be of less value at a different time point.

Clinical utility of QOL data

Although the collection of QOL data is frequent in research settings, the frequency of its use in clinical settings is increasing with the FDA and national guidelines recommendations for PRO integration in clinical care [14,42,43,95,96].

One important component of usability is the definition of a "clinically meaningful difference" for a measure. Studies with large sample sizes may find high levels of significance between groups with small, clinically insignificant mean differences. Several strategies are being used to overcome the risk of spurious significant findings based on small differences between large cohorts. Accepted distribution-based strategies consider a meaningful difference to be a change in scores or a difference between groups of one-third to half a standard deviation of the observed scores [97,98]. Increasingly, Cohen's *d* is utilized with continuous data to determine the effect size, that is, the strength of differences between groups or change from small (≥0.2), or medium (≥0.5) to large (≥0.8) based on the calculation of the difference between the means of two groups divided by the standard deviation of the control or comparison group, or the pooled standard deviation of the two groups [99]. Other clinically validated strategies to determine differences between groups is to use anchor or cutoff point scores defined within specific instruments. The EORTC QLQ-C30 defines cut point differences of 5, 10, and 20 points as small, medium, and large effects, respectively [100]. A recent meta-analysis has provided interpretation guidelines for the clinical significance of mean differences on the FACT-G, with about 2 points on subscales indicating small clinically meaningful differences and 5 points on the total score indicating clinically meaningful differences [101]. Similarly, the PHQ-9 depression measure defines "mild" depression as scores of 5–9, "moderate" as

10–14, "moderately severe" as 15–19, and "severe" as 20 or above. These cut point scores translate to treatment recommendations, with 10–14 supporting consideration of treatment and 15 or above indicating that consideration of pharmacologic and/or non-pharmacologic treatment is probably warranted. The scores can be used in research to define eligibility for study entry or as a pre-set indicator of treatment efficacy.

Monitoring and discussion of QOL with HCT recipients have the potential to increase patient involvement in care, reassure patients, and improve patient satisfaction. Use of QOL assessments can improve physician–patient communication and enhance patient QOL outcomes [14,102]. Good-quality QOL data specific to a patient's type of treatment, gender, and other risk factors can aid patients in making informed treatment choices [103].

Generic measures

There are three QOL measures routinely selected when providing a "generic" assessment of cancer-related QOL outcomes: the Functional Assessment of Cancer Therapy – General (FACT), the European Organization for Research and Treatment of Cancer (EORTC) Quality of Life Questionnaire C30, and the Short Form 36 Health Survey (SF-36), which is not a cancer-specific measure. One or more of these is commonly used in most cancer QOL studies. Each of these well-standardized, reliable, and valid measures has some questions in common with the others and also asks some unique questions. Each has been used effectively in HCT research. The FACT assesses physical, social/family, emotional, and functional wellbeing. The EORTC, in contrast, has a more explicit focus on functional abilities, what a patient is able to do physically, and specific symptoms, and a rather brief psychological review. There is no psychometric evidence to recommend one of these measures over the other; rather, differences in scale structure and content of the questions, and the measure best suited to the study hypotheses, are important to consider when selecting between these two cancer-specific QOL assessment tools [104,105]. The SF-36, meanwhile, is a health-related QOL measure not specific to disease [106]. Its evaluation of physical ability corresponds most closely to that of the EORTC [107]. It provides a brief assessment of psychological function, and it has minimal emphasis on physical symptoms. Given its general health orientation across populations and lack of symptom evaluation, the SF-36 is appropriate for use in the years post-transplant as issues become less HCT symptom-specific.

Research has documented that these QOL measures are correlated but do not share enough variance to be considered equivalent [107]. Investigators find that the instruments have analogous global health items (correlation $r = 0.82$), but the physical, psychological and social dimensions of the EORTC and FACT share only limited variance [104,107]. Luckett et al. provided a detailed comparison of the two measures [104].

Each of these measures has normative information on use with HCT. Each has translations into multiple languages, and all are appropriate to capture issues faced by HCT patients. These scales have particular value for their abilities to provide a normative reference for a sample or an individual patient. For comparison, Table 33.2 lists the subscales for these three QOL measures.

HCT-specific measures

Both the FACT and the EORTC have add-on modules that are specific to HCT. The FACT-BMT asks questions specific to treatment. It does not evaluate physical abilities per se. The BMT module of added questions contains items that elaborate the more common HCT symptoms and concerns [108]. The EORTC also has an HCT-specific module, the EORTC QLQ-HDC29, which measures side effects and HCT-specific issues [109].

Table 33.2 Subscales of the most widely used adult global health-related QOL measures, reliability and validity established in HCT populations

	EORTC QLQ-C30	FACT-BMT	SF-36
Subscales	Physical functioning Emotional functioning Social functioning Role functioning Cognitive functioning Global quality of life Pain Nausea/vomiting Fatigue EORTC QLQ-HDC29	Physical wellbeing Functional wellbeing Emotional wellbeing Social/family wellbeing BMT module	General health Physical function Role – physical Body pain Vitality (inverse of fatigue) Mental health Role – emotional Social function
Summary scores	Subscales only	Total score and subscales	Physical composite T-score Mental health composite T-score
Number of items	30 in core 29 added in EORTC QLQ-HDC29	27 in core 18 added in BMT module	36

Since generic measures may not have the sensitivity to capture the factors of interest in a clinical trial, measures specific to hypothesized outcomes may need to be added to a generic tool. Considering symptom and function outcomes helps to clarify this point. Patients can be assessed for general physical function with a measure such as the EORTC or SF-36, but if an intervention is targeted explicitly to reduce fatigue these scales may not have the sensitivity to capture outcome changes, although both the FACT and SF-36 have been found to be sensitive to the effects of cGVHD [16].

A construct central to cancer QOL and HCT specifically is the concept of disease- and treatment-specific distress: what are the worries, stresses, or fears specific to a patient having a transplant that contribute to how he or she is doing? Studies find that HCT-specific distress is a better predictor of pain, nausea, and stress responses during acute treatment than is depression or other general mood indicators [40,41], while depression is a better predictor of long-term outcomes [1].

Two US National Institutes of Health resources can be great assets to investigators wishing to select measures specific to a QOL construct. The Patient-Reported Outcomes Measurement Information System (PROMIS) initiative provides a database of standardized and effective PRO measures including such outcomes as fatigue, pain, emotional distress, physical function and psychosocial function. The Grid Enabled Measures (GEM) Database through the National Cancer Institute provides a web-based platform for searching for standardized measures within QOL constructs such as physical function, anxiety, depression, or social relationships. By searching in GEM, not only can an investigator identify relevant measures, but the site also offers descriptions, the targeted populations, and psychometric properties such as reliability and validity. Both of these sites are open to the public through an online search.

QOL measurement methods

Given the large number of QOL measures translated for age and language, it should be possible for the majority of patients to complete a general QOL measure appropriate to their needs in writing or online if they can read. The gold standard for QOL assessment is a patient completing written or computer assessment with a staff person who is available to answer questions and to assure that the patient is competent and responding as instructed, and also to review responses and correct skipped or double responses while the patient is present. Alternatively, most measures can be administered by mail, orally, and by telephone if necessary. Testing of QOL assessment across modalities with HCT or other cancer patients substantiates the transferability of written measures to a tablet, computer, or mobile device [110–112]. Measures are equally reliable and valid with written, mailed, and computer formats [62,110–112]. Completeness and quality of data are improved with the computer administration of measures [62,111]. Online assessments reduce both staff and patient burden by providing checks for missed items, they eliminate double responses, and they can include intentional skip patterns to reduce the number of items (e.g., a female does not have to answer questions intended only for males). In contrast, at least one error occurred in 44% of paper response forms. Patients generally prefer the electronic response version once they try it. If in-person or online assessment is not possible, mailed assessments are equally valid and reliable. If telephone or proxy responses with someone answering for the patient become necessary, responses are not as consistent or valid as with the other methods, but are generally accepted.

Pediatric QOL assessment

When selecting pediatric QOL, there are several assessments to consider. The Pediatric Quality of Life Inventory (PedsQL) includes both a patient report and a parent report evaluating QOL for pediatric cancer patients on dimensions parallel to the FACT or EORTC [113–115]. Multiple versions suited to the developmental ages of children are comparable. A companion Cancer or Transplant Module provides treatment-specific assessment of symptoms. An alternative is the Child Health Ratings Inventory (CHRIs), with its Disease-Specific Impairment Inventory-HSCT (DSII-HSCT; a transplant-specific module). Preliminary studies in HCT cohorts indicate good reliability, and moderate correlations between child and parent reports of QOL [116,117].

Proxy or parent

When a patient is unable to provide a self-report of QOL, a proxy responder or missing data may be the only choices. A proxy is usually a nurse or caregiver, or most often the parent of a young child. Research on the validity of proxy responses indicates that parents and other proxies differ in responses when compared with patient reports [77,113,117]. Proxies, including parents, tend to underestimate patients' symptoms. In contrast, they tend to rate global QOL and mental health lower than patient self-reports [77,117]. Fortunately, proxies are more accurate when they are rating concrete, observable events.

Conclusion

QOL before, during, and after HCT has been well described. Studies agree that most patients regain high levels of physical, psychological, and functional QOL by 1–3 years following transplantation. At the same time, a subset of patients will have medical problems, such as cGVHD, that impinge on long-term QOL. Even for patients who return to full-time work and normal social activities, and those who have good psychological and physical function, specific areas of difficulty often remain. Recognized long-term problems include fatigue, cognitive deficits, musculoskeletal symptoms, and sexual dysfunction for both males and females. The impact on QOL of medical late effects is receiving more attention but remains an area deserving of further investigation.

By nature, QOL shifts with the situation a patient is in, reflecting not only observable abilities, but also expectations for the immediate circumstance. As a result, very ill patients can report good QOL in some areas. In assessing QOL, many measures have been tested with adult and pediatric HCT patients and work well. A generic QOL measure provides valuable normative information that permits a comparison of scores with patients of comparable age, gender, and/or disease. At the same time, specific, focused measures such as those for fatigue, sexual function, or distress may be needed to provide adequate sensitivity when defining the nature of a target problem or to detect clinical trial differences. Fortunately, there are many effective examples of QOL assessments that have been tested with HCT patients, at all ages and phases of treatment and survivorship. Online modalities are increasingly becoming the preferred form for assessment. Finally, a remaining challenge is to determine a method that facilitates the use of QOL data in clinical decision-making.

CHAPTER 34

Sexuality Following Hematopoietic Cell Transplantation

D. Kathryn Tierney
Stanford University Medical Center, Stanford, CA, and University of California San Francisco, San Francisco, CA, USA

Introduction

A sentinel paper on the outcomes of 107 recipients of allogeneic hematopoietic cell transplantation (HCT) was published in 1975 by Dr. E. Donnall Thomas and colleagues [1]. Nine of the individuals transplanted for acute leukemia survived at least 1 year and 16 individuals transplanted for severe aplastic anemia became long-term survivors. Outcomes of transplantation have improved significantly since that early report. These improvements are due to advances in many fields, including blood banking, tissue typing, detection and treatment of infectious complications, pharmacology, immunology, and supportive care. As outcomes have improved, the use of HCT as a therapeutic modality has increased. Current estimates of the number of transplants performed worldwide are approximately 55,000–60,000 per year with an estimated 150,000 HCT survivors five or more years post-transplant [2,3]. HCT survivors and professional organizations including the American Society of Blood and Marrow Transplantation, the Center for International Blood and Marrow Transplantation Research, the Oncology Nursing Society, the Institute of Medicine, and the National Comprehensive Cancer Network have called on healthcare providers to focus efforts on addressing long-term medical and health-related quality of life (HRQOL) issues [4–7].

Investigations into the HRQOL of HCT survivors have spanned over two decades. While the majority of HCT survivors report good to excellent HRQOL, approximately 5–20% report persistent problems that negatively affect their well-being, including fatigue, cognitive dysfunction, chronic graft-versus-host disease (GVHD), musculoskeletal symptoms, and alterations in sexual health [8]. An important HRQOL concern of HCT survivors and the focus of this chapter is changes in sexual health resulting in sexual dysfunction and dissatisfaction. It is clear that the twofold mandate of HCT is both cure of the underlying disorder and preservation of quality of life.

Sexuality is explored as a multidimensional construct with biologic, physiologic, psychologic, and social dimensions. This conceptualization of sexuality remains a salient framework for assessing alterations in sexual health. Intervention strategies for sexual dysfunctions are presented and opportunities for future research are explored.

Conceptualizing sexuality

The World Health Organization views sexuality as an integral component of the human experience, which can enrich and enhance personality, communication, and love [9]. Sexual functioning, reproductive capabilities, and body image are three distinct and interrelated aspects of sexuality [10]. Sexuality includes the image one holds of oneself as a sexual being and gender roles, the concept of what it means to be a man or a woman [11]. Sexuality is shaped by age, developmental stage, culture, beliefs, expectations, sexual preferences, past intimate relationships and experiences, and the sexual partner(s). Sexuality is expressed in appearance, attitudes, values, roles, relationships, and sexual activity [11,12]. Although the diagnosis and treatment of a life-threatening illness may alter sexuality and sexual expression, they do not eliminate the need of individuals for intimacy, affection, and emotional connection to others. The theorist Abraham Maslow in his hierarchy of human needs placed love, belonging, and intimacy immediately after physiologic needs and safety [13].

The *Diagnostic and Statistical Manual of Mental Disorders* describes sexual dysfunctions based on the phases of the human sexual response cycle. Excitement, plateau, orgasm, and resolution are the four phases of the sexual response cycle as initially described by Masters and Johnson, and later Kaplan introduced desire as a unique phase [14,15]. The corresponding disorders of these phases include hypoactive sexual desire disorder (HSDD), female arousal disorder, erectile dysfunction (ED), orgasmic disorders, and sexual pain disorders (vaginismus and dyspareunia) [16]. There are two key components to the diagnosis of sexual dysfunctions: first, a physiologic or psychologic change that negatively impacts sexual functioning, and second, the association of this change with intra- or interpersonal psychologic distress [16].

Alterations in sexual health following HCT

Sexual dysfunctions reported in male HCT survivors include HSDD, ED, delayed or absent orgasm, and ejaculatory problems. Female HCT survivors may experience HSDD, arousal disorders, orgasm disorders, dyspareunia, and menopausal symptoms secondary to premature ovarian failure (POF). Table 34.1 reviews the incidence of sexual dysfunctions, which varies across studies based on time since transplant, sample characteristics, and study instruments. Longitudinal investigations specifically focused on altered sexuality indicate that sexual dysfunctions are common and often long lasting [17–19]. In 102 HCT survivors evaluated pre-HCT and again 12 and 36 months post-HCT, both men and women experienced an increase in sexual dysfunctions over time [17]. For male HCT survivors, the

Table 34.1 Investigations of altered sexual health following HCT

Ref.	Study details	Measurement(s)	Findings
[57]	*n* = 36 females Mean age 26 years (range 14–43 years) Mean 4 years post-HCT (range 8 months to 9 years)	1. Questionnaire regarding menopausal symptoms, sense of femininity, sexual difficulties, social activities, and coping 2. Interview for effects of hormone therapy on symptoms	61% hot flashes 36% night sweats 81% vaginal dryness *Problems in 22 sexual active women:* 73% decreased desire 64% orgasm problems 82% problems with sexual intercourse
[93]	*n* = 44 females Median age at evaluation 30 years (range 18–43 years) Median days post-HCT 357 (range 261–4628 days)	1. Physical examination 2. Laboratory studies 3. Gynecological examination 4. Interview for menopausal symptoms and sexual functioning	*Received radiation and chemotherapy:* 67% hot flashes, night sweats, insomnia, and mood changes *Received chemotherapy only:* 38% hot flashes, night sweats, insomnia, and mood changes *In 30 sexually active women:* 77% vaginal dryness 53% diminished libido and arousal 60% dyspareunia 70% diminished pleasure Gynecologic findings: tissue atropy, loss of pubic hair, small uterus, introital stenosis and atrophic vulvo-vaginitis
[48]	*n* = 37 females Mean age 30 years (range 17–46 years) Time from HCT 13–84 months	1. Gynecologic examination 2. Hormonal assessment	83% vasomotor symptoms (hot flashes, sweating, irritability) 76% vaginal dryness and dysuria 76% dyspareunia 70% sexual problems (decreased desire, altered self-image, anxiety, decreased self-confidence)
[34]	*n* = 51 men Mean age 33 years (range 19–49 years) Mean time from HCT 58 months (range 6–154 months)	1. Investigator-designed questionnaire on sexual function 2. Hospital Anxiety and Depression Survey 3. Hormonal assessment	15% diminished desire 24% ED 13% delayed ejaculation 9% dry ejaculation 20% premature ejaculation
[92]	*n* = 126 females and males Mean age 27 years (range 9 –50 years) Mean 47 months post-HCT (range 6–149 months)	1. "Faces" Scale of Life Satisfaction 2. Hormonal assessment when possible	24% ED 13% ejaculation difficulties 22% of all subjects reported diminished sexual satisfaction
[50]	*n* = 15 females Mean age 22 years (range 17–30 years) Assess pre-HCT and 3–4 months post-HCT	1. Hormonal assessment 2. Pelvic ultrasound 3. Interview	53% hot flashes 25% cystitis symptoms 25% irritability 33% mood changes 73% depression 40% diminished libido 53% dyspareunia
[47]	*n* = 74 post-pubertal female allogeneic HCT survivors Median age 30 years Mean 49 months post-HCT (range 4–118 months)	1. Gynecological examination 2. Hormonal assessment 3. Interview regarding HRT, menopausal symptoms, and sexual activity	78% hot flashes 61% genitourinary symptoms 94% of 52 sexually active women reported difficulties with intercourse Gynecologic findings: vulvo-vaginal atrophy, loss of pubic hair, decreased thickness of genital mucosa
[35]	*n* = 29 men Mean age 35 years (range 18–61 years) Mean 36 months post-HCT (range 7–97 months)	1. Psychosexual Functioning Questionnaire – male version 2. Psychosocial Adjustment to Illness Scale 3. Hormonal assessment	38% diminished desire 21% altered body image 38% ED 48% sexual dissatisfaction
[94]	*n* = 31 females and males Median age 38 years (range 16–56 years) Assessed pre- and 3 months post-HCT	1. Derogatis Interview for Sexual Functioning	*Pre-/3 months post-HCT:* 36/48% sexual dysfunction 65/52% sexual dissatisfaction 36/40% decreased desire 14/11% arousal problems 43/43% orgasm problems 25/25% ED
[95]	*n* = 64 females and males Median age 39 years (range 20–65 years) Mean 52 months post-HCT (range 19–89 months)	1. EORTC QLQ-C30 2. Leukemia-BMT specific module 3. Questionnaire on sexual functioning and fertility 4. Questionnaire on patient perception of changes in HRQOL	*Autologous/allogeneic HCT survivors:* 21/60% diminished desire 30/68% decreased sexual activity 18/47% decreased pleasure 29/53% diminished ability to engage in sexual activity
[20]	*n* = 168 females and males Median age 33 years Median time from HCT 14 months	1. Questionnaire on sexual functioning and fertility 2. EORTC QLQ-C30 3. Patient ranking of perceived changes in sexual relationships	*Autologous/allogeneic HCT survivors:* 44/51% decreased desire 48/57% decreased sexual activity 27/42% decreased pleasure 29/45% decreased sexual ability
[96]	*n* = 16 men Mean age 36 years (range 20–49 years) Median of 3 years post-HCT (range 7–96 months)	1. investigator-modified Psychosocial Adjustment to Illness scale 2. Hormonal assessment	25% diminished desire 12% intermittent ED

(*Continued*)

Table 34.1 (*Continued*)

Ref.	Study details	Measurement(s)	Findings
[77]	*n* = 30 females Mean age 37 years (range 25–49 years) Mean time with ovarian failure 16.6 months (range 6–36 months with an additional subject 4 years and another 9 years)	1. General and gynecological examinations 2. Complete blood count, liver function tests, lipid panel, hemostasis parameters, hormone levels 3. Medical history 4. Pelvic ultrasound, mammography, and computerized bone mineralometry 5. Investigator-designed questionnaire for menopausal symptoms	90% vasomotor symptoms, hot flashes, night sweats, and palpitations 54% vulvo-vaginal atrophy with dyspareunia, itching, and burning 54% mood changes with anxiety, depression, irritability, and headache 45% atrophic skin changes 42% urinary tract symptoms 26% weight gain 16% insomnia 16% memory changes Gynecologic findings: cervical and uterine atrophy, loss of pubic hair, pale mucous membranes, vaginal dryness, stenosis, and decreased vaginal elasticity
[31]	*n* = 70 Median age at time of study for men 43 years (range 24–59 years) Median age at time of study for women 45 years (range 23–59 years) Median 81 months post-HCT for men and 76 months for women (range 18–198 months for men and 17–219 months for women)	1. EORTC QLQ-C30 2. Global health status 3. Hormonal assessment	44% overall decline in QOL 56% of men and 61% of women decline in sexual relations 47% more ED than pre-HCT 38% of men absence of orgasm 38% ejaculatory dysfunction 53% vaginal dryness 19% dyspareunia and delayed or absent orgasm

incidence of ED increased from 13% to 22% and arousal problems rose from 15% to 20%. Arousal problems in women climbed from 40% at baseline to 52% by 3 years. Problems with lubrication and pain increased from 30% to 52% and from 14% to 33%, respectively. In a 5-year longitudinal assessment of sexual functioning in allogeneic HCT survivors, HSDD was noted in 44% of women and 23% of men [18]. Additional findings from this study indicated that 27% of men reported problems with ejaculation and 23% experienced ED. Of the female HCT survivors, 40% described vaginal dryness, 16% dyspareunia, and 44% difficulties with orgasm. A compelling feature of this study was the use of case-matched controls. At 5 years post-HCT, 80% of female HCT survivors had one or more sexual problems compared with 61% of the female control group and 46% of male HCT survivors reported sexual problems compared with 21% of the male control group. Another longitudinal evaluation reported ED in 33% of men pre-HCT, increasing to 50% at 1 year and then declining to 22% at 3 years [19]. The incidence of ejaculatory dysfunction remained stable across the three assessments at 22%. Men also experienced an increase in problems with orgasm from 13% before HCT to 22% at 3 years post-HCT. For women, the problems with vaginal dryness, dyspareunia, and orgasm all worsened from pre-HCT levels. The incidence of vaginal dryness increased from 49% to 72%, dyspareunia from 29% to 55% and problems with orgasm from 46% to 72%.

Findings indicate that female HCT survivors are more likely to experience sexual dysfunction than male survivors [17–20]. Important to note from these longitudinal investigations is the incidence of sexual dysfunction in both men and women pre-HCT. Although sexual dysfunctions increase in incidence post-HCT, problems clearly begin prior to transplant. These studies also highlight the concern that alterations in sexuality do not improve over time and interventions are needed early in the transplant recovery phase to maximize benefit and minimize the risk that alterations in sexuality will become chronic problems.

Etiology of altered sexual health in HCT recipients

Alterations in sexual health may be due to a number of biologic, physiologic, psychologic, and social variables and the complex and dynamic interactions among these variables. Consequently, the origins of sexual problems will rarely be isolated to a single etiology. Physiologic changes due to the cancer or treatment may result in sexual dysfunctions, as will psychologic distress. Social variables influencing sexuality include the relationship with the sexual partner(s), difficulties in establishing new intimate relationships, role changes, and the health of the sexual partner.

Biologic and physiologic variables in men

The etiology of ED, an inability to achieve or maintain an erection sufficient for satisfactory sexual intercourse, may be hormonal, vascular, neurologic, pharmacologic, psychologic or a combination of these factors [21,22]. High-dose preparatory regimens can damage the hypothalamic–pituitary–gonadal axis and thyroid leading to hormonal changes that can alter sexual functioning in men. The hypothalamus secretes gonadotropin-releasing hormone (GnRH) into the circulation, stimulating the release of gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) from the pituitary. FSH and LH control gonadal function resulting in the production of gametes and the synthesis of the sex steroids testosterone and inhibin. The Leydig cells under the influence of LH start androgen synthesis and secretion. FSH initiates spermatogenesis, which is then maintained by testosterone [23,24]. Negative feedback to the hypothalamus and pituitary occurs when testosterone and inhibin levels rise, blocking the secretion of GnRH and the gonadotropins [25]. Both radiation and chemotherapy damage gonadal tissue, leading to decreased secretion of the sex steroids and thus a loss of the negative feedback inhibition at the level of the hypothalamus and pituitary. The result is elevated levels of FSH and LH indicative of infertility [23].

The degree of gonadal damage will depend on age, the dose of radiation and chemotherapy, and the type of chemotherapy administered [23,26,27]. Radiation directly to the testes in doses of 12–15 cGy produces irreversible azoospermia [24]. Radiation and chemotherapy, particularly alkylating agents, result in a dose-dependent depletion of the germinal epithelium lining the seminiferous tubules of the testes, and this depletion results in azoospermia, testicular atrophy, and infertility [26,28]. Features of germinal cell depletion consist of small testicular size and reduced testicular volume [26]. Endocrine values in men with germinal cell depletion include elevated FSH (25–90 mIU/mL), elevated LH (8–25 mIU/mL), low to low normal testosterone (200–700 ng/100 mL), decreased testosterone production rate (3.5 mg/day), and decreased free testosterone (8.6 ng/100 mL) [26].

Most men following high-dose preparative regimens, particularly those including total body irradiation (TBI), will become infertile as a result of damage to the hypothalamus–pituitary–gonadal axis. However, infertility following high-dose therapy is not always a certainty. In a study evaluating the hypothalamic–pituitary–gonadal axis of 31 men following a high-dose chemotherapy-only preparatory regimen, 11 men agreed to semen analysis [27]. Following allogeneic transplant, four men were azoospermic, five were oligospermic, and one had a normal sperm count. Additionally, one man following autologous HCT also had a normal sperm count.

Testosterone is strongly correlated with sexual desire and arousal [29]. Levels of testosterone in male HCT survivors may remain within normal limits as the Leydig cells are believed to be relatively resistant to the effects of chemotherapy and radiation [24,30]. In a report of gonadal function following preparative regimens consisting of high-dose chemotherapy without TBI, six men had high basal LH levels with low total testosterone whereas 10 men had high basal LH levels with normal total testosterone [27]. Another investigation reported that of 26 men who received a preparative regimen containing TBI, all had elevated FSH levels, 20 had normal LH levels, 21 had low normal testosterone levels, and five had reduced testosterone levels [31]. More extensive hormonal evaluation may reveal subtle damage to the Leydig cells, evidenced by a reduction in the amount of testosterone produced [32]. Findings from one study indicated that men receiving allogeneic HCT are at higher risk for low testosterone levels than autologous HCT recipients [27]. Men over the age of 45 years may be at increased risk of testosterone insufficiency [33]. Elevated prolactin has been noted in some men following HCT [28,34] and is associated with infertility, ED, and decreased libido [21,29,34,35]. Hypothyroidism or subclinical hypothyroidism secondary to TBI may contribute to reduced levels of free testosterone and bioavailable testosterone [28,36,37].

Cavernosal arterial insufficiency has been reported as a cause of ED, with the risk higher in those men receiving TBI than in those who received chemotherapy only [38]. Pelvic irradiation can cause penile arterial insufficiency or blood vessel adhesions contributing to ED [21,28,38–40].

Hypertension contributes to ED in healthy men [21,37] and is a common side effect of calcineurin inhibitors utilized for GVHD prophylaxis and treatment. ED and diminished intensity of orgasm may be caused by chemotherapy agents associated with peripheral neuropathies administered prior to HCT or with the HCT preparative regimen [41]. Other lifestyle factors that may contribute to ED include cigarette smoking, alcohol use, and high cholesterol levels [21,42]. Sirolimus (Rapamune), which is used for GVHD prevention and treatment, commonly causes hyperlipidemia. Chronic GVHD may cause an increase in the sensitivity of penile skin, rash, or inflammation adding to sexual dysfunction [40]. Fatigue, decreased physical stamina, loss of muscle mass, and joint problems are common following HCT and can disrupt all phases of the sexual response cycle.

Biologic and physiologic variables in women

In women, damage to the hypothalamic–pituitary–gonadal axis secondary to a high-dose preparatory regimen is well established. Damage to the ovaries by high-dose preparative regimens results in a loss of estradiol secretion. As in men, the hypothalamus secretes GnRH into the circulation, stimulating the release of the gonadotropins FSH and LH from the pituitary. FSH initiates growth and maturation of the ovarian follicles and LH controls ovulation and corpus luteum formation [23]. Negative feedback to the hypothalamus and pituitary occurs when estradiol levels rise, inhibiting the secretion of GnRH, FSH, and LH [25]. Both radiation and chemotherapy damage ovarian tissue, leading to decreased secretion of estradiol and thus a loss of the negative feedback inhibition to the hypothalamus and pituitary. In women, findings of elevated levels of FSH and LH are indicative of infertility and ovarian failure [23,27].

The degree of gonadal damage will depend on age, the dose of radiation and chemotherapy, and the type of chemotherapy administered [23,26]. Alkylating agents and radiation therapy have cytotoxic effects on both dividing and resting ovarian cells. A single high dose of TBI produces ovarian failure in all women [23]. Evaluation of ovarian function following chemotherapy-only preparative regimens found evidence of gonadal failure in all recipients of allogeneic HCT and 95% of autologous transplant recipients [27]. Serial ultrasound examinations have demonstrated that almost immediately following high-dose preparative regimens, the ovaries show evidence of structural damage, shrinkage, and loss of follicles [33]. In a group of 41 women at a mean of 1.5 years (range 0.2–9.8 years) post-HCT, ultrasound examinations showed ovarian gland atrophy, absence of follicles, and a small uterus [27]. In addition to decreased levels of estradiol and elevated levels of FSH and LH, a small number of women tested had evidence of abnormal androgen function [28]. Hypothyroidism or subclinical hypothyroidism secondary to TBI may also contribute to POF [28,36,43].

Estrogen deficiency is associated with a multitude of symptoms, including hot flashes, night sweats, insomnia, mood swings, irritability, depression, changes in cognitive function, altered appearance, reduced bone density, and cardiovascular disease [30,44,45]. In the absence of estrogen, the vaginal mucosa becomes thinner with less lubrication, leading to itching, dryness, burning sensations, an increased risk of infections, and dyspareunia [45,46]. Urogenital tissues deprived of estrogen results in dysuria, urinary frequency, incontinence, and an increased risk of urinary tract infections [46,47]. The sudden loss of estrogen secondary to a high-dose preparative regimen may result in more pronounced or severe symptoms of estrogen deprivation [45,48].

Multiple factors contribute to alterations of vaginal tissue, including the effects of POF, the preparative regimen, in particular TBI, and chronic GVHD of the vagina. Radiation may contribute to vaginal narrowing and stenosis [28]. In one report, nearly half of the 61 women studied reported vaginal chronic GVHD by 2 years following HCT [49]. Features of vaginal chronic GVHD include inflammation, ulceration, stricture formation, narrowing and obliterated introitus, and symptoms of cystitis and excoriation [49–52]. The mean onset of vaginal chronic GVHD was 10 months with a risk period of 2 years [51].

Interference in all phases of the sexual response cycle can be caused by fatigue, decreased physical functioning, loss of muscle mass, and joint problems, which are common problems for HCT survivors.

Psychologic and social variables

Psychologic distress, including depression [53–55], anxiety [53,54,56], decreased self-confidence and self-esteem [57,58], altered body image [19,33,35,57,59], and grief secondary to infertility [20,57,60], is reported by some HCT survivors and this distress can be long-lasting. Depression measured both pre-HCT and 3 years later was a significant predictor of sexual dysfunction in men and women [19]. In men, higher levels of psychologic distress pre-HCT significantly predicted for sexual dissatisfaction 3 years post-HCT [17]. Psychologic and relationship stress can contribute to ED [21]. Regardless of the biologic or physiologic causes of ED, there is an accompanying psychologic distress, including reduced self-esteem, decreased sense of masculinity, and embarrassment [22]. In women, POF is more than a physiologic transition into menopause but is associated with a number of psychologic stresses, including feelings of lost youth and femininity, altered body image, and loss of fertility [24,45,61].

Infertility may alter a woman's sense of femininity and a man's sense of virility and masculinity [11,62]. Infertility and alterations in gender roles may result in a loss of self-confidence [33,57,59,62]. Younger individuals and those couples who have not completed childbearing are likely to experience more personal and relationship distress secondary to infertility. Couples' concerns regarding infertility may not decline over time and coming to terms with infertility requires active discussion and problem solving [60]. Single individuals may be hesitant to establish new intimate relationships for fear of rejection secondary to infertility [63].

Body image changes includes those alterations apparent to others such as scars, alopecia, weight changes, skin changes due to chronic GVHD, scleroderma, joint contractures, open wounds, and Cushingoid features secondary to corticosteroids used for the prevention and treatment of GVHD. Just as importantly, body image changes include changes not apparent to others, such as the image the HCT survivor holds of him- or herself as a sexual being. Findings from one study indicated that 56% of men and 55% of women report feeling unattractive 3 years after HCT [19].

The long road from the diagnosis of a life-threatening illness through recovery following HCT is physically and psychologically challenging. During transplant and the early recovery phase, a caregiver is required who assumes significant responsibility for the care of the HCT recipient. Often this caregiver is the sexual partner. The effects of role changes on intimate relationships are not fully understood. Several publications have cited the burdens of caregiving and the significant problems faced by caregivers. A longitudinal investigation evaluating marital satisfaction indicated that the spousal caregivers experienced higher levels of depression and anxiety at 6 and 12 months post-HCT than the HCT survivor [64]. Additionally, marital satisfaction scores declined for the caregiver from pre-HCT to the 1-year assessment, whereas marital satisfaction scores for the HCT survivor remained stable. The decreased marital satisfaction scores were significantly more pronounced if the caregiver was female. In another study evaluating the HCT survivor, caregiver, and a matched control group for late effects, the HCT caregiver experienced more fatigue, sleep problems, cognitive dysfunction, and sexual problems than controls [55]. This study also reported that the incidence of depression for the HCT survivor and caregiver was ≥20% compared with an 8% incidence in the matched control group. HCT caregivers also reported less social support, marital satisfaction, and spiritual well-being than the HCT survivors or controls and were less likely to receive psychologic care.

Resuming sexual activity following treatment may be difficult for some couples. The HCT survivor may be struggling with physical recovery, psychologic distress, body image changes, fatigue, and concerns about their sexual functioning. The sexual partner may also be struggling with fatigue, psychologic distress, altered sexual health, and the increased burdens of caregiving and responsibilities at home. Psychosocial adjustment of HCT survivors is influenced by the presence or absence of social support or the perception of social support [58,65,66]. Social support and strong family relationships have been found to facilitate adjustment and an absence of social support negatively influences adaptation even years after transplant [65,67]. If a major source of social support for the HCT recipient is the intimate partner and relationship stress arises due to alterations in sexual functioning, then the recovery process may be jeopardized.

Assessment and interventions for altered sexual health

One investigation reported that 30% of HCT survivors were not informed of potential alterations in sexuality and 20% were not satisfied with the information they received on fertility and sexual functioning [31]. In a second study, half of the participants followed over 3 years indicated they had no discussion of sexuality with their healthcare providers [19]. Silence by healthcare providers remains a significant and persistent barrier to addressing sexuality. Healthcare providers cite personal discomfort, lack of education, the sensitive nature of the topic, fears of embarrassing the patient, and limited time as reasons for failure to discuss sexual health [12,39,68]. Healthcare professionals can eliminate these barriers by gaining an understanding of the impact of HCT on sexuality, utilizing standardized assessment tools, identifying educational resources for HCT survivors, and developing a referral network. Despite the sensitive nature of sexuality, when asked, HCT survivors will often discuss sexual concerns as freely as they will discuss other HRQOL issues [18].

The first intervention to address sexual health is a pre-HCT discussion of the risks of infertility, POF, symptoms of menopause, and possible alterations in sexual functioning, which is all part of informed consent. An essential component of this dialog is offering reassurance that there are effective interventions should problems in sexual functioning occur. Education is the first step in establishing expectations for life after transplant and beginning the process of adaptation [69]. Research has shown that HCT survivors experience higher levels of psychologic distress when there is a discrepancy between their expectations and their experiences [54]. Simply informing couples that decreased libido is common for many months following HCT is a simple place to start. The healthcare provider should whenever possible include the sexual partner with the aim of facilitating communication, identifying the partner's anxieties, and enlisting the partner's support. The pre-HCT conversation legitimizes sexuality as a valid area of concern and identifies the healthcare provider as a resource for the couple. Early interventions are critical based on a growing body of evidence that sexual dysfunctions following transplant do not appear to get better simply with the passage of time [17,18].

Written education materials can be valuable resource for HCT survivors and the sexual partner and should specifically address when it is safe to resume sexual activity, what precautions are needed, possible changes in sexual functioning, when to consult a healthcare professional, and a list of resources. Many organizations have websites that offer information on sexuality, including the American Cancer Society, the American Urological Association, Cancer Care, Cancer Supportive Care Programs, Fertile Hope, the Lance Armstrong Foundation, the National Cancer Institute, the Oncology Nursing Society, Sexuality Information and Education Council of the United States, and the Wellness Community [70].

Although a discussion of altered sexual health may be sufficient to address the concerns of many HCT survivors, others may be experiencing sexual dysfunctions that require a referral to a specialist.

Transplant centers should identify a group of experts for referrals that includes a urologist, endocrinologist, gynecologist, reproductive specialist, psychologist, relationship (marriage) counselor, and possibly a sex therapist. A simple approach to begin an assessment of sexual health is to ask patients if they have resumed sexual activity. The routine use of a standardized assessment tool for follow up visits will help familiarize healthcare providers with the appropriate language to use for sexuality and increase their comfort level with this sensitive topic [71].

Assessing for any psychologic distress secondary to infertility is required, so that appropriate referrals can be initiated. Pre-HCT options for attempting fertility preservation include sperm or oocyte cryopreservation, cryopreservation of testicular or ovarian tissue, hormonal suppression of ovarian function, and embryo cryopreservation, and post-HCT options include in vitro fertilization, donor oocyte or donor sperm, and embryo transfer [24,72]. Ideally, the referring hematologist or oncologist will have had discussions on fertility preservation prior to the referral for transplant as the majority of individuals will arrive at the transplant center having already received therapy that may affect fertility. Recent findings that recovery of spermatogenesis may occur even following some high-dose preparative regimens places additional obligations on the HCT team to provide adequate counseling regarding birth control and the prevention of unplanned pregnancies.

Hypoactive sexual desire disorder

Sexual desire is the least well understood and the most difficult aspect of altered sexual health to treat. Desire is strongly linked to the second phase of the sexual response cycle, arousal, hence individuals with HSDD may also experience problems with arousal. In men, testosterone is known to influence sexual desire, but the role of hormones and desire in women is not well understood. Newer models of the sexual response cycle suggest that for women, desire for sexual activity may follow the arousal phase and be motivated by the need for emotional closeness with her partner [73].

The evaluation of HSDD must include a review of physiologic and psychosocial variables. Physiologic assessment includes a physical examination focusing on fatigue and physical stamina as well as hormonal testing. Emotional distress, particularly depression, is a key factor to be evaluated in both the HCT survivor and the sexual partner. If depression is identified as a contributing factor, antidepressant therapy may be helpful; however, the selection of the antidepressant is critical. Both selective serotonin reuptake inhibitors and serotonin–norepinephrine reuptake inhibitors are associated with decreased sexual desire [74]. The risk of sexual dysfunction is up to 2.5 times greater for women taking antidepressants [74,75]. Newer antidepressants with different mechanisms of action may actually improve sexual desire [76].

The relationship with the intimate partner needs to be evaluated for stress, discordance of expectations, and adequacy of communication. One transplant center has had success in improving sexual activity using couple-based therapy focused on communication, education, and intimacy [40].

In assessing HSDD, it is important to determine if decreased sexual desire preceded or developed as a consequence of other sexual dysfunctions, as HSDD is common in both men and women experiencing other sexual dysfunctions [69]. If, for example, a man is experiencing ED or a woman is experiencing dyspareunia, both of these problems may contribute to HSDD. Therapeutic interventions will need to be targeted at treating contributing sexual dysfunctions and not specifically focused on the HSDD.

In male HCT survivors with low to low normal testosterone levels, testosterone replacement therapy (TRT) can be effective in improving sexual desire [27,38]. Testosterone therapy in women is controversial; however, some women may experience improvements in sexual desire and arousal with androgen therapy [29,39,77].

Premature ovarian failure, vaginal atrophy, and dyspareunia

Assessment of women with POF includes medical history, physical and gynecologic examination, hormonal evaluation and medication profile. The hormonal testing should include estradiol, FSH, LH, androgen level, and thyroid function tests. Many symptoms of estrogen deficiency can be ameliorated or minimized with hormone replacement therapy (HRT). HRT is effective in relieving hot flashes, improving sleep, maintaining vaginal elasticity and lubrication, and decreasing changes in the appearance of the skin and breasts. Multiple studies of female HCT survivors have reported relief of menopausal symptoms following HRT [27,47,48,57] with improvements in most symptoms noted within a short period of time [77]. Based on the effective and rapid resolution of symptoms, HRT should be offered to female HCT survivors after assessing for possible contraindications such as chronic GVHD of the liver or a history of blood clotting problems. One investigator has suggested that initiation of HRT within the first year following HCT is critical to avoiding long-standing issues of sexual dysfunction [17].

The findings of the Women's Health Initiative Study reporting that the risks of breast cancer, heart attack, stroke, and blood clots outweigh the benefits of HRT in women following physiologic menopause is a source of anxiety for some individuals [78]. The risks of HRT in female HCT survivors may not be the same as those in women following physiologic menopause. For females with POF, HRT is administered to compensate for the premature loss of endogenous hormones [24,79]. In general, women with POF should utilize HRT until the age of physiologic menopause [79].

The benefits of HRT in relieving symptoms of estrogen deficiency are clear; however, the choice of HRT is challenging and requires a committed gynecologist and additional study. Selection of the HRT should be guided by the woman's symptoms, preferences, and risk factors for complications from HRT and designed to prevent future complications such as osteoporosis [77]. One group's recommendation for women who are only recently estrogen deficient is low-dose estrogen for the first month, increased to full dose in the second month [79]. However, if she has been estrogen deficient for 12 months or longer, then low-dose estrogen replacement should be initiated with a gradual increase to maintenance doses by 6 months to avoid side effects. A recommended estrogen dose for young women with POF is the equivalent of 1.25 mg of conjugated equine estrogens combined with progestins if the uterus is present [79]. Some oral contraceptives may reduce circulating free testosterone, resulting in diminished sexual desire [29]. In women with adequate estrogen replacement and complaints of diminished desire, fatigue, and a poor sense of wellbeing, androgen therapy may be beneficial [77,79].

Non-hormonal strategies for relieving symptoms of estrogen deficiency include herbs, vitamins, yoga, acupressure, acupuncture, exercise, and diet modifications. Few of these interventions have been rigorously tested. A systematic evidence-based review found Remifemin, a formulation of the herb black cohosh, to reduce hot flashes [80]. Antidepressants can ameliorate hot flashes. Venlafaxine (Effexor) reduced hot flashes by 60% and other antidepressants that may be helpful include paroxetine

(Paxil), fluoxetine (Prozac), and citalopram (Celexa) [81,82]. Gabapentin (Neurotin), clonidine hydrochloride (Catapres), and bellergal (Bellergal-S) have also been reported to decrease hot flashes [82]. The North American Menopause Society is an excellent web-based resource for women.

Female HCT survivors with vaginal atrophy, narrowing, and dyspareunia may benefit from the use of vaginal lubricants and dilators. Vaginal lubricants should be water soluble to avoid the risk of infections. Vaseline is not water soluble and therefore should not be used. K-Y Jelly (Johnson and Johnson, New Brunswick, NJ, USA), vitamin E, Replens (LDS Consumer Products, Cedar Rapids, IA, USA), and Astroglide (Biofilm Inc., Vista, CA, USA) provide lubrication for sexual intercourse. Astroglide has been reported by some users to last longer during sexual activity. Additionally, Replens can be used to restore moisture to vaginal tissues. One applicator of Replens can be inserted into the vagina three to four times per week at bedtime to restore moisture. These products can be found at most drug stores or via the Internet.

Dilators can be obtained from a gynecologist or through the radiation therapy department. Women should lubricate and then insert the dilator into the vagina until she experiences slight discomfort. She should leave the dilator in place for 10–15 minutes three to four times per week. As the vaginal tissues begin to stretch, the depth of penetration and size of the dilator can be gradually increased. The level of commitment for pursuing these measures in a consistent manner will optimize results. Pelvic floor strengthening exercises guided by a pelvic physical therapist may reduce vaginal pain. Women experiencing dyspareunia should assume a position during sexual intercourse that allows her to control both the rate and depth of penetration, enabling her to stop if she becomes uncomfortable. Women worried about lubrication and their response to sexual stimulation can be encouraged to masturbate, as a way to explore their response without simultaneously being concerned about their partner's needs [83].

Evaluation of the medication profile and adjustment of medications may improve sexual functioning, as many medications adversely affect sexual functioning, including anti-androgens, sedatives, antidepressants, and stimulants [84].

A comprehensive program for the prevention of chronic GVHD of the vagina incorporating patient education, topical estrogen, early initiation of HRT, vaginal dilatation in the absence of sexual activity, and regular gynecological examination minimized the development of severe GVHD of the vagina in a series of 61 women [49]. The investigators also outlined treatment for established chronic GVHD of the vagina, which included topical steroids, topical cyclosporine, and vaginal dilatation in women who had evidence of vaginal narrowing. Fifteen of the 28 women had complete resolution of symptoms, eight noted improvement and in five the symptoms remained stable. None of the women required surgery, which is in contrast to other reports were surgical interventions were necessary [51].

Erectile dysfunction

The assessment of ED requires a medical history and physical examination, a review of the medication profile, knowledge of coexisting health problems and lifestyle factors, and hormonal testing, which includes total testosterone, bioavailable testosterone, sex hormone-binding globulin, FSH, LH, prolactin, and thyroid function [21,38]. A comprehensive evaluation of the functional and structural capacity of the penis is required for men with ED [85].

TRT often restores sexual desire and arousal and may also improve erectile function [29,38]. In one report, TRT restored testosterone levels to normal after 2 years of therapy, allowing discontinuation of the hormone replacement [27]. The men in this study reported improved sexual functioning, sexual desire, and wellbeing. TRT is available as an intramuscular injection, transdermal patches, gel and oral forms. Testosterone enanthate (Delatestryl) and testosterone cypionate (Depo-Testosteron) with a recommended dose of 100–200 mg intramuscularly every 2–4 weeks are two options [21,85]. TRT is contraindicated in men with a history of prostate cancer and routine monitoring of prostate-specific antigen levels should be performed at 6-month intervals [86]. TRT may contribute to coronary artery disease by its effect of lowering high-density lipoproteins [85]. Hyperprolactinemia observed in some male HCT survivors is associated with decreased desire and ED and can be effectively treated with bromocriptine mesylate (Parlodel) [87].

Performance anxiety can lead to ED and subsequently HSDD. Suggesting masturbation may improve a man's confidence in his erectile function without simultaneous concerns about his partner's needs [83]. Erectile function will be improved by staying very focused on sensations during sexual activity to minimize negative thoughts and performance concerns and prolonging foreplay will ensure maximum arousal.

Many classes of medications, including antihypertensives, anticholinergics, antihistamines, cardiac medications, antidepressants, alcohol and other recreational drugs can contribute to ED. A review of the medication profile is a component of the assessment for the etiology of ED. Reducing doses or trying alternative medications may result in improved sexual functioning.

The phosphodiesterase inhibitors sildenafil (Viagra), vardenafil (Levitra) and tadalafil (Cialis) have made an important contribution to the effective treatment of ED. Phosphodiesterase inhibitors do not increase sexual desire but improve penile response to sexual stimulation. Sildenafil (50–100 mg) and vardenafil (10 mg) should be taken approximately 1 hour prior to sexual activity. Tadalafil (10–20 mg) has a longer half-life and is generally taken 30 minutes to 12 hours prior to sexual activity. In 2008, tadalafil (2.5–5 mg) was approved for once-daily dosing for men anticipating more frequent sexual activity [88]. The phosphodiesterase inhibitors are generally safe and well tolerated; however, the concurrent use of nitrates is an absolute contraindication [22]. A number of other strategies for the treatment of ED include intracavernosal injections, transurethral therapy, vacuum devices, and surgical interventions, but in general these strategies are not as well accepted [39].

One group of investigators hypothesized that a combination of TRT with sildenafil would improve erectile functioning in men following HCT [89]. The sample consisted of eight men aged 22–58 years and 2–24 months post-HCT with evidence of hypogonadism, ED, decreased libido, ejaculatory disorders, and documented cavernosal arterial insufficiency. The men were treated with a combination of TRT given monthly for 6 months and sildenafil taken once or twice per week. Results indicated that all eight men had improvements in erectile function allowing satisfactory sexual intercourse, seven men had resolution of ejaculatory dysfunction and all had improvements in both total and free testosterone levels. The authors concluded that this combination therapy is a safe and effective therapy for ED in HCT survivors and should be evaluated in a larger clinical trial.

Areas for future research

The interventions presented for the treatment of sexual dysfunctions in HCT survivors are based on clinical expertise and the literature of sexual dysfunctions in other cancer survivor populations and in healthy individuals. There remains a paucity of research focused on interventions to restore sexual health in HCT survivors. Designing and testing an education program to help HCT survivors and their spouses/partners develop realistic expectations of life after HCT including alterations in sexual health may bring expectations and outcomes closer together and thereby decrease psychologic distress. Investigations are needed to develop insights into the effects on intimate relationships when the spouse/partner is the caregiver and interventions to decrease the psychologic distress of caregiving need testing. Exploration of the biologic, physiologic, and psychosocial variables that underlie alterations in sexual health needs to continue with the aim of designing treatment interventions. Identification of variables that can predict which HCT survivors are at risk for alterations in sexual health is necessary. The effects of reduced intensity conditioning regimens on fertility and sexual health have not been fully explored. Testing the use of TRT plus a phosphodiesterase inhibitor in a larger sample of men suffering from ED post-HCT would be valuable. Future research must include a diverse population of HCT survivors that includes the elderly, adolescents, same-sex couples, and diverse ethnic groups. Development of validated instruments that can be easily incorporated into time-limited clinic appointments will advance the treatment of sexual dysfunctions. As infertility may not be a certainty, resources should be devoted to systematic follow-up of pregnancy outcomes.

Conclusion

Sexuality is a broad concept encompassing much more that sexual activity and remains an important aspect of being human, regardless of the diagnosis and treatment of life-threatening illness. The understanding of alterations in sexual health following HCT is not complete. It is clear that the etiology of sexual dysfunctions for both male and female HCT survivors has biologic, physiologic, and psychosocial components and complex and dynamic interactions among these variables.

Research findings have been presented suggesting that there are effective interventions for the treatment of POF symptoms, HSDD, vaginal chronic GVHD, and ED. Although additional investigations are needed, these results are clinically relevant now and can be utilized to address this critical aspect of HRQOL. After a pre-HCT discussion of sexuality, the next step is to include an assessment of sexual health as part of routine care following HCT. It has been shown that an open discussion of sexuality with a healthcare professional can be therapeutic and address many areas of concern. Developing a referral network of other healthcare professionals, including gynecologists, urologists, reproductive specialists and mental health professionals, enables the HCT team to assist HCT survivors with alterations in sexual health.

Although the focus of this chapter has been sexual dysfunctions, it must be stated that many HCT survivors report satisfying sexual relationships after transplant [90–92]. The challenge for the HCT team is to identify those HCT survivors who are experiencing sexual dysfunctions and intervene. If the transplant team can improve the HRQOL of HCT survivors by addressing issues of sexual health, one of the two mandates of transplantation will be met.

CHAPTER 35

Hematopoietic Cell Transplantation: The Patient's Perspective

Susan K. Stewart

Blood & Marrow Transplant Information Network (BMT InfoNet), Highland Park, IL, USA

> *I still find it almost bizarre that I would be the one to get so sick. I was very physically active. I rode my bike 2000 miles a year, swam about 100 miles and was active in my children's lives. Leukemia happens to people you read about in the newspaper during their appeals for donors or money for transplants. It doesn't strike enormously healthy, happy and vital 39-year-old family men.*
>
> HCT survivor Mike Eckhardt, 1995

Preparing for transplant

Like Mike, most people have never contemplated the notion that they may some day have an illness that requires treatment with hematopoietic cell transplantation (HCT). Regardless of whether a patient is newly diagnosed or previously learned of the illness and has exhausted other therapies, the prospect of HCT is traumatic for both the patient and his or her loved ones.

Having lived through this experience myself in 1989, after being diagnosed with acute myelogenous leukemia, I know first hand how difficult it can be to process information under duress, make life or death decisions, and cope emotionally with the HCT experience. In 1990, I created Blood & Marrow Transplant Information Network (BMT InfoNet; http://bmtinfonet.org/services/support) to help other families navigate the HCT experience. Through lay-language books about HCT, survivorship symposia, and peer counseling, BMT InfoNet services more than 10,000 patients and their loved ones each year. Their experiences helped inform this chapter.

Patients are overwhelmed with fear: fear that the transplant will not cure; fear that the transplant might kill; fear of pain; and fear that the side effects of treatment will be intolerable. Many are also angry and/or depressed over the loss of control over their wellbeing. A disease now controls their body, and the patient must rely on a team of strangers to save his or her life. Preparing a patient for the rigors of HCT against this backdrop of fear, anger, and/or depression is challenging. Some patients are so overwhelmed emotionally that they hear and process little of what a physician tells them. They can process only discrete packets of information, are overwhelmed by details, and prefer to leave much of the decision-making in the hands of the physician.

At the other end of the spectrum are the patients who attempt to regain control over their body by accumulating as much information as possible about their disease and treatment options. They want complete, detailed information about the risks and benefits of treatment. They will search external sources, such as the Internet, for information. They want to be fully engaged as partners in their care.

Since patients' styles of coping with troubling medical information vary greatly, it is important to ascertain in advance how much information a patient wants, and how best to deliver it. Level of education, cultural biases about discussing illness and death, the degree of trust that a patient has in the medical establishment, and individual coping styles will define the best method of discussing treatment options with a patient. Asking how much detail the patient wants when discussing medical treatments, and whether he or she prefers to hear it all at once or in small segments, enables a physician to tailor the delivery of information to best suit each individual patient.

Despite these differences, there are certain universal elements of communication that are helpful to bear in mind when preparing a patient for transplant.

Put the risks into perspective

When a patient meets with the transplant team, a long list of potential treatment-related complications is described. For many, this is the first time they have heard a detailed discussion of the risks associated with HCT. The prospect of developing these complications is frightening for patients, and many leave the consult with the transplant team more depressed than when they arrived.

> It was like a whirlwind, a dream. One day our child was a normal 15-year-old boy who would live to be 80. The next day we were staring at blackboard diagrams about transplants, and hearing doctors tell us our son might die. It wasn't real. We didn't understand. All we could do was hug each other and cry. (Lorraine Boldt, mother of transplant survivor)

Patients need help putting the risks associated with HCT into perspective. Grouping the complications into (a) those that always occur, (b) those that often occur, and (c) those that seldom occur provides patients with a manageable framework for understanding relative risks and coping emotionally with the prospect of complications. Knowing that the risk of developing severe liver damage is small, while the risk of developing mucositis is high, for example, conveys a far more accurate picture of what a patient should expect. Without such a framework, patients may imagine the risk of developing very serious complications to be greater than it is.

It is also important to distinguish between those side effects that are temporary and those that may persist long term. Most people

Thomas' Hematopoietic Cell Transplantation, Fifth Edition. Edited by
Stephen J. Forman, Robert S. Negrin, Joseph H. Antin and Frederick R. Appelbaum.
© 2016 John Wiley & Sons, Ltd. Published 2016 by John Wiley & Sons, Ltd.

believe they can deal with a problem for a discrete period of time. Knowing in advance what the normal range of duration is for each complication enables patients to cope better with the difficulty when it arises. Without such information, patients can become distressed if a complication persists, and may become concerned that it signals relapse, disease progression, or another serious problem.

It is equally important to discuss how complications will be managed. Although a detailed discussion of each therapy is not necessary, patients should know that treatment for each complication exists. This is particularly important when discussing painful complications, since some patients fear pain more than death. Many patients do not automatically assume that pain medication will be available to relieve discomfort. This must be explicitly stated. Leave out this discussion and a patient can assume that he or she will suffer tremendous pain, or that the complication is not treatable, and this can increase the emotional load.

Communication in lay language

Although many patients are well educated, most are unfamiliar with the medical terms used routinely by transplant personnel. Terms such as "CBC," "aspirate," "Hickman," "bilirubin," "TPN," and even "stem cells" are often foreign to people without medical training. Even more commonly used words such as "prognosis" and "remission" may be meaningless to patients who have never used these terms. Most patient advocacy groups, and also the general print media, strive to use language that can be understood by a person with a fifth- or sixth-grade education. Given that HCT patients are under a great deal of emotional stress and may not be able to process information as easily as the average person, medical procedures and terms should be described as simply as possible. In the absence of a clear explanation, patients may misinterpret the message being conveyed by the physician.

Using precise language also improves a patient's understanding of what he or she is about to experience. For example, when describing a painful procedure, using words such as "hurt" or "pain" does not adequately prepare a patient for the sensation he or she will feel. Terms such as "pressure," "stinging sensation," or "dull ache" convey a more precise idea of the sensation. Precise language will help reassure patients that these sensations are normal when they occur.

Repetition and reinforcement are important

The volume of information that HCT patients receive is overwhelming, and few completely digest the information during the first presentation. Patients who are emotionally overwhelmed may shut out complicated or frightening information, and later recall only part or nothing of what was said.

It's important to repeat information at several points during treatment. A patient who was unable to absorb critical information when it was initially presented may be better prepared to absorb it later after the initial shock about the diagnosis and the difficult treatment he or she is about to undergo wanes. Some patients have found video- or audiotaping the initial consultation with the transplant physician to be helpful. Such a record enables them to double-check their understanding of what was said later when reflecting upon the information. It also helps them catch important details they may have missed during the initial presentation. Suggesting this option to patients can provide them with a valuable tool, and can reassure them that the physician wants them to be as informed as possible about the impending treatment. Suggesting that patients bring a support person to the consultation whose sole purpose is to take notes can also be helpful. Proactively suggesting this in addition to taping the conversation will help those who might be too distraught to think of these tools on their own.

Encouraging patients to ask questions can also enhance understanding. Some patients come from a cultural background where questioning a physician is considered rude or disrespectful. Inviting them to ask questions to confirm their understanding can give them "permission" to do so. Inviting questions means more than simply saying, "Do you have any questions?" Inviting questions in a way that elicits more than a yes/no answer may allow patients to formulate and state their concerns better. For example, a physician might say, "Some patients don't understand what I mean when I say they will become neutropenic. Do you understand what I mean by neutropenic, or should I explain it more clearly?" Such a question normalizes a confusion the patient may have and affirms the physician's responsibility to make the explanation as clear as possible.

Patients who have questions during treatment sometimes do not feel that they have an adequate opportunity to present them to the physician. Creating an atmosphere that encourages questions from patients is essential. A physician who appears busy or distracted can discourage patient questions without meaning to do so, leaving the patient feeling anxious and uninformed. Sitting down when entering a patient's hospital room, for example, signals to the patient that the physician has time to focus on the patient's concerns. Consciously making an effort to engage a patient in conversation, rather than simply delivering news, can create an atmosphere that elicits patient concerns. Suggesting that the patient maintain a notebook of questions that arise when the physician is not present can also help patients organize their thoughts.

Different learning styles

It is well accepted by educators that individuals have different styles of processing information and learning. A person who is primarily a *visual learner* does best when charts or pictures accompany the explanation. Seeing the person with whom he or she is talking, rather than just hearing an explanation, enhances understanding. An untidy environment can interfere with this patient's ability to absorb information.

Auditory learners, on the other hand, do best with verbal explanations. They are more likely to use telephone support systems, such as help-lines, than pore over charts or diagrams that explain a problem. They are easily distracted by sounds.

Kinesthetic learners learn by doing. They like hands-on explanations and can be distracted by movement.

When educating transplant patients, accommodating the variety of learning styles is important. A person who is primarily a visual learner can miss key information if the education plan relies solely on verbal explanations. Patients who are primarily auditory learners can have difficulty absorbing print information. Kinesthetic learners may benefit from a tour of the facilities where procedures will be performed, with an opportunity to handle equipment that will be used during transplant.

Although it may be difficult to ascertain each individual's learning style, providing the patient with a menu of learning tools will maximize the likelihood that he or she will absorb important information. Augmenting verbal explanations of procedures with written publications or audiovisual aids produced by organizations such as BMT InfoNet or the National Marrow Donor Program (NMDP) (www.marrow.org) enables a patient to choose the information vehicle that best suits his or her needs.

Discussing pain control is important

Many patients fear pain even more than death. However, although all transplant teams inform patients about potential complications, some neglect to discuss the steps that will be taken to manage pain. They assume that patients know that pain medication will be administered as needed. Many patients, however, have had little experience with hospitalization and painful medical procedures, and do not automatically assume that pain relief will be available. Others have undergone painful medical procedures without adequate pain control and have little reason to assume that pain will be managed more effectively by the transplant team.

Explicitly telling patients that pain control medications will be used to prevent and control pain, and educating them about when to ask for pain relief, can ease their anxiety. Many patients try to be stoic, asking for pain medication only after pain becomes intense. Explaining that pain is easier to manage before it becomes intolerable, normalizing the use of pain medications in the transplant setting, and encouraging patients to request relief before pain becomes unbearable can minimize the discomfort and anxiety that a patient experiences. If a patient-controlled analgesia device will be available, letting the patient know that he or she will have some control over the administration of pain medication can make the prospect of pain more manageable.

It is equally important to warn patients and caregivers in advance about possible side effects of pain medications. Most are unprepared for the change in mental status that accompanies the use of some medication, and both patients and caregivers can become alarmed when this occurs. Patients can see or hear things that are not real and talk nonsensically. Caregivers who observe this without understanding that this is a side effect of the medication, and patients who later realize they have been hallucinating, can become emotionally distraught. Assuring both patient and caregiver that these drug reactions are within the range of normal and are temporary can alleviate unnecessary anxiety.

Fear of addiction discourages some patients from asking for pain relief. Patients, and also many physicians, do not realize that drug addiction is a psychologic phenomenon, whereas drug dependence is a physical phenomenon. Although a patient may develop a physical dependence on a drug, he or she can be weaned from it by tapering the dosage. An addiction, however, requires psychologic interventions to address the underlying cause of the addiction, in addition to tapering or discontinuation of the drug. Patients who have never had a drug addiction are unlikely to develop an addiction to pain medications administered as part of HCT [1].

Discuss psychologic difficulties

An important area of patient education that is often overlooked is a discussion of the psychologic difficulties that patients and family members encounter during transplant. Patients may be told that the transplant will be a “difficult” or “stressful” experience, but these words fail to describe or normalize the type and depth of emotions the patient and his or her family are likely to experience.

If not given this information, a patient becoming angry or depressed during treatment and recovery may assume that there is something wrong – that he or she is a weakling or is not coping as well with the stress as most patients. After all, the patient reasons, if these emotional difficulties were common among HCT patients, the medical team would have said so in advance, just as they warned of the other medical complications. Some become angry with themselves for not coping well, which exacerbates their emotional distress.

As difficult as the transplant experience is for patients, it can be even more difficult for the family member/caregiver who is keenly aware of the patient’s progress or lack thereof. The person upon whom the caregiver normally relies for support – the partner – may be the patient, who is ill equipped to deal with anyone’s emotional load besides his or her own. Usual support networks, such as family members or friends, may fail to comprehend the severity of the situation and be unprepared to address the caregiver’s needs.

It is important that the healthcare team be explicit with both the patient and caregiver about the range of emotions they may experience during and after transplantation. Anger about the disease, resentment over the loss of control of the patient’s wellbeing, fear about medical procedures or possible treatment failure, and depression about the slow pace of progress are typical emotions that patients and caregivers face. The patient may express distress by lashing out at the medical team or a loved one. Assuring both patient and caregiver that these emotions are normal, and explicitly telling them what types of assistance are available to help them cope, maximize the likelihood that they will seek and accept help, should they need it.

Patients need to understand that HCT is an extraordinary experience and that they can expect to need more than their everyday coping tools to manage the stress. Normalizing the use of antianxiety or antidepressant medications in this circumstance, and assuring the patient that, in the absence of a history of substance abuse, drug dependence is not likely, can alleviate patients’ concerns about using these tools.

For some patients, the acute care period is the time of greatest stress. For others, the post-transplant period poses the greatest psychologic challenge. The support system provided by the hospital and medical personnel has been curtailed, the busy daily schedule of tests, doctor visits, and other hospital routines is now replaced by long days of isolation and inactivity, and the challenge of resuming a normal lifestyle can be daunting.

> When I left the hospital, I thought the tough part was over. I’ve never been so wrong. The inpatient part was the easiest part of the bone marrow transplant process. I was focused and fired up… All the worldly things, such as my role as a husband and father, were secondary to winning the inpatient battle. Other routine things such as house payments, medical bill, career, and church weren’t even on my mind. Nurses and doctors took care of me. It wasn’t easy, but I felt I was making significant progress toward beating my disease.
>
> The clarity of purpose and sense of progress were lost when I came home. Instead of feeling like a successful patient, I felt like a failed person. All those worldly things, such as my roles as husband and father that I had ignored in the hospital, came roaring back. They were once again important and I felt woefully inadequate in those roles.
>
> The steroids and cyclosporine made me extremely emotional and irrational. I would cry because I had too much milk on my cereal. I couldn’t sleep (steroids), couldn’t shower (Hickman), couldn’t read (no concentration), couldn’t drink coffee in the morning (nausea), couldn’t exercise (no strength) and couldn’t get close to my children (might get an infection). Even taking my medicine was confusing and overwhelming. I spent time worrying about things I couldn’t control. I was convinced I was going to run out of money, lose my house, my dog, etc. There was no measured progress anymore. I felt I was regressing. I was in an emotional rut. [2]

Emotional difficulties can surface weeks or months after transplant. Unexpected rehospitalization for a complication can cause distress. Some experience symptoms similar to post-traumatic stress syndrome: a sight or smell may trigger an unpleasant memory of the transplant experience, leaving the patient shaken.

Returning to work, school, or a social world that has moved on during transplantation can make a patient feel isolated. Fear of relapse causes many patients to avoid long-term planning. It can take many months before a patient is able to get through a single day without thinking about the transplant.

A study has confirmed what many caregivers report: the intensity and duration of transplant-related distress are in some ways greater for caregivers than for patients long term [3]. The caregiver must deal not only with his or her own fears about the patient's health, but also with those of other family members. The caregiver may be thrust into new roles, assuming responsibilities once handled by the recovering spouse. These tasks, coupled with his or her own emotional turmoil, can create significant distress. Some who handled the acute phase of transplant well find themselves emotionally drained and unable to function fully many months later:

> In some ways, it was like we were no longer married. We were never alone. Our whole relationship – everything – was based on illness, medical procedures, hospital, and family. Trying to resume a normal relationship was not possible. Family was continually around – always. I understood, but some days I didn't want to share my husband. I wanted him all to myself.
>
> I had to take over all of his responsibilities – paying bills, yard work, etc. Instead of being an equal partner, it was like having another child to worry about. I felt like I'd lost the man I married and just wanted him back.

Psychosocial support networks for patients and their families

A number of support networks are available for families facing the emotional challenges associated with transplant. BMT InfoNet has a Caring Connections Program that links HCT patients and family members with survivors who can provide emotional support. Patients and survivors are paired according to diagnosis, type of transplant, and other factors the patient may deem important such as gender, transplant center, religion, etc. Survivors are screened to ensure they provide emotional support, rather than medical information, and the pairs communicate by telephone or email. This service is particularly helpful for patients who do not have access to email, or prefer not to communicate by that means. Patients can access this service at www.bmtinfonet.org/patient.html.

Many patients and family members find "list-servs" on the Internet helpful. A list-serv is an electronic mailing list that enables a person to discuss issues with a large number of peers online, and to offer and get support. The list-serv is managed by an individual who typically screens postings before emailing them to the entire list, although the screening is generally limited to weeding out commercial solicitations and hostile emails. Members can opt to receive individual emails from other members after they have been posted, or a daily digest of emails that enables them to determine, by the subject heading, whether any of the issues discussed in the posts are of interest to them. Patients can respond to a posting on the list-serv by emailing the entire list or by privately emailing the individual who posted it.

Discussions on HCT-related list-servs are lively, and many patients find the list-serv an invaluable place to vent their feelings and concerns with others who understand and will empathize. A great strength of list-servs is that they can validate a person's feelings, and normalize his or her experience. A downside is the potential for sharing medically inaccurate or inappropriate information, although patients can easily verify the information with their own physician. More often, valuable information about medical interventions that have worked with other patients is shared which the patient can discuss with his or her physician.

The Association of Online Cancer Resources (ACOR) (www.acor.org) maintains a list-serv for HCT patients (BMT-Talk), one for patients with graft-versus-host disease (GVHD), and list-servs organized by diagnosis. Anyone can subscribe via the ACOR website by following the links under Mailing Lists.

A real-time online chat room also exists for HCT patients and caregivers. BMT-Support (http://bmtinfonet.org/resources) meets several times weekly. There are separate chat rooms for patients and for caregivers. Participants log in at the specified time, and the live online chat is moderated by a survivor with nursing training.

Disease-specific organizations, such as the Leukemia & Lymphoma Society and the International Myeloma Foundation, offer local or online support programs for patients. Although some transplant patients find these helpful, others find discussions with people who have not undergone a transplant unsatisfying. A list of organizations that provide disease-specific information and support can be found on BMT InfoNet's website at www.bmtinfonet.org/resource.

General support groups for caregivers are offered by the Well Spouse Foundation (www.wellspouse.org) and by general cancer support organizations such as Cancer Support Community (www.cancersupportcommunity.org), the Wellness Community (www.thewellnesscommunity.org), and local cancer support centers.

Young adult patients often find resources targeted to their age group helpful. The Ulman Cancer Fund for Young Adults (www.ulmanfund.org) provides a peer support program similar to BMT InfoNet's Caring Connections Program. Young adults can be linked with others whose life has been affected by transplant and read their stories online. The fund also provides educational scholarships to young adults diagnosed with cancer.

Some patients or their family members require individual counseling to help deal with their emotional distress. Although transplant centers may provide psychiatric help and counseling while the patient is undergoing transplant, that support system is often unavailable when patients return home. It can be difficult to find a local mental health professional who is experienced in dealing with cancer- or transplant-related issues. The American Psychosocial Oncology Society (www.apos-society.org) offers a help-line for patients and families seeking a local specialist who is trained in working with cancer patients and can address their needs.

Quality of life post-transplant

From the patient's perspective, successful HCT does not simply mean that the patient survives. It also means that he or she resumes a reasonably normal life after transplant. Significant survivorship challenges are often not discussed during the acute phase of treatment, and even at discharge patients may not be adequately prepared for the psychologic stress that ensues. They may also not be equipped with coping strategies for medical difficulties such as depression, infertility, cognitive problems, chronic fatigue, and sexual difficulties that can occur after HCT.

In 2006, BMT InfoNet invited HCT survivors and their family members to complete an online survey to determine issues of concern to survivors post-transplant. Invitations were issued by email to persons on the *Blood and Marrow Transplant Newsletter* mailing list, and via the home page of BMT InfoNet's website.

A total of 580 persons completed the survey. Respondents identified themselves as:

- an HCT survivor – 68%;
- the parent of a survivor – 12%;
- the spouse/significant other of survivor – 11%;
- the child of a survivor – 1%;
- the sibling of a survivor – 1%;
- other (caregivers or transplant center staff) – 8%.

Some 40% had an autologous transplant, 34% had an allogeneic transplant with a related donor, and 26% had an allogeneic transplant with an unrelated donor.

Respondents reported their last date of transplant as follows:

- 2001–2006 – 55%;
- 1996–2000 – 25%;
- 1990–1995 – 17%;
- pre-1990 – 3%.

When asked which issues, based on their experience, were most important to transplant survivors, respondents checked the following options (more than one answer being allowed):

- emotional/psychologic health of transplant survivor – 72%;
- detecting and preventing long-term complications – 71%;
- fatigue – 63%;
- emotional/psychologic health of the survivor's family – 50%;
- chronic GVHD – 49%;
- learning and memory problem – 46%;
- health insurance – 44%;
- educating local physicians about transplant survivors' needs – 43%;
- secondary cancers – 41%;
- sexuality after transplant – 37%.

In response to an open-ended question, survivors expressed frustration over the lack of resources to deal with the psychologic burden after transplant, including significant depression. They also expressed concern with problems that interfered with their ability to resume work or school and function effectively, such as cognitive deficits or fatigue. Input from this survey was used to develop a 1-day survivorship symposium for HCT survivors in Oakbrook, IL, in April 2007. Presentations by experts on fatigue, psychosocial problems post-transplant, cognitive issues, chronic GVHD, sexuality, infertility, insurance, and employment issues were featured. About 350 survivors and caregivers from throughout the United States attended this educational event, which also featured psychosocial support groups where survivors could network with each other.

For most, this was the first opportunity post-transplant to hear presentations on issues that were significantly impacting their daily life, such as psychosocial difficulties, cognitive issues, and insurance issues, and to discuss them with other survivors. Not only were their experiences validated, but also they learned tools for managing some of the problems. Evaluations were overwhelmingly positive, and more forums of this type were requested.

Many who attended the session on infertility remarked that they had been poorly equipped by their transplant program for this side effect of treatment. Not only had prophylactic measures, such as sperm banking, been ignored in some cases, but few resources were offered them when it was confirmed that they were infertile, either because of prior treatment or because of the transplant. One attendee reported that she had not been advised that infertility was a potential complication of transplant. For some patients, the prospect of infertility post-transplant is as upsetting as the diagnosis itself. Disappointment over the prospect of infertility is not limited to patients who have never had children but extends to some individuals who already have children and would like to expand their family.

Patients' emotional distress can be lessened if they are advised that it is sometimes possible to conceive a child post-transplant. Men may be able to bank a sufficient quantity of viable sperm before treatment to allow attempts at pregnancy post-transplant, provided that prior therapy has not led to aspermia. Some women may be able to conceive a child with assisted reproduction techniques and a donor oocyte. Although these steps do not guarantee a successful pregnancy, the technology is improving each year, and it comforts many patients to know that there is at least a chance of conceiving or carrying a child to term.

Even if a woman does not become infertile immediately after transplantation, the chemotherapy or radiation administered as part of the HCT can reduce the number of viable oocytes and cause her to become prematurely menopausal later on. Therefore, women who wish to conceive a child post-transplant should be counseled that their window of opportunity may have shortened, and plans for pregnancy should be pursued as early as practical [4].

Many transplant survivors experience significant, long-term changes in sexuality following treatment. Problems including lack of libido, inability to perform, and pain are reported by persons with both normal and abnormal hormone levels post-transplant. As one man stated, "It seems like my brain has been cut off from the rest of my body. I can conjure up all sorts of juicy sexual images in my brain, but can't get the rest of my body to perform."

Changes in sexuality can seriously stress a relationship, particularly if the survivor's partner believes that the problem is purely psychologic rather than physical. Although fatigue and psychologic trauma do, indeed, affect sexuality, it is important that patients and their partners know that physical changes occur following transplant that may also affect the survivor's sexuality. Patients should be advised that they may need to develop new approaches to intimacy after transplant to enable both partners to have a satisfying sexual relationship. Patients should be encouraged to report sexual difficulties and be provided with referrals to experts who may be able to help resolve some of the problems.

A significant issue that is often overlooked in discussions with patients is changes in cognitive abilities they may experience, both short and long term. Much has been written about learning difficulties observed in children following HCT, but little note has been taken of the cognitive changes experienced by some adult HCT survivors. Problems reported by survivors include poor concentration, memory problems, stuttering, difficulty in spelling, inability to perform jobs that were previously mastered, and difficulty in learning new tasks. Many survivors have been able to overcome the problem by changing the way in which they manage information, such as making lists, writing down all appointments, keeping notes, and so forth. For others, the solution is not so simple, and the problem may interfere with their ability to perform a job or learn a new skill.

One survivor who was a sculptor said, "Before my HCT, conceptualizing the design and drawing it was the most difficult part of my work. When it came to the actual sculpting, I could do it without even thinking. However, after my HCT, I could barely concentrate on the sculpting. Conceptualizing and drawing the design became impossible. No one has been able to explain why this happened, or suggest what I can do to relieve the problem."

One woman who underwent high-dose chemotherapy and autologous HCT was delighted that her company held her computer operator job for her while she underwent treatment. However, when she returned to work 4 months later, she found that the nature of the job had changed and she needed extensive training to perform the new tasks. After 2 weeks of training, she feared she would be fired. As she explained, "When I'm at work and in training, all the explanations make perfect sense. But then I come home, fix dinner, and clean up. When I sit down to review the day's lesson I'm totally confused. By the following morning, I've completely forgotten everything I learned the previous day."

Although most patients do not develop cognitive problems as severe as those experienced by the two persons described above, patients should be advised that changes in cognitive abilities sometimes occur. If cognitive problems do develop, survivors will be less frustrated if they know that their problem is not unique. Advance warning about this potential problem can also relieve tension in the home. Tired and distraught family members will understand that the survivor's new forgetfulness is not simply laziness, but a consequence of the treatment.

Chronic GVHD

Survivors with chronic GVHD face a unique set of challenges post-transplant that can severely impact their quality of life. Preliminary results of a 2007 survey conducted by BMT InfoNet of more than 300 transplant survivors who have or had chronic GVHD found that chronic GVHD interfered with the daily activities of nearly two-thirds of patients and nearly 40% of other family members; 41% reported financial difficulties as a result of chronic GVHD, and nearly one-third reported marital difficulties; 57% of survivors with chronic GVHD reported sadness or depression, and 41% said the mental health of other family members had also been negatively impacted.

Survivors with significant chronic GVHD often feel isolated. There are few HCT support groups available for patients after transplant, and disease-specific support groups seldom include a significant number of survivors who have been through transplant, let alone those who have experienced chronic GVHD. Improvements in treatment are rare, and opportunities to network and learn from other survivors are limited.

For those with Internet access, a list-serv on ACOR provides a forum for patients with chronic GVHD. List members discuss their symptoms, therapies they have tried to manage them, and clinical trials in which they have participated. Often, a newly diagnosed person or a list member who has become overwhelmed with the difficulties presented by chronic GVHD shares their distress with list-mates, and the outpouring of emotional support is impressive.

When the patients with chronic GVHD surveyed by BMT InfoNet were asked what resources would be helpful, 98% said a central website with chronic GVHD information, 93% said a print newsletter about chronic GVHD, and more than 8% said a DVD with information about chronic GVHD, a local meeting with transplant doctors to discuss chronic GVHD, or a local support group would help. BMT InfoNet is exploring the feasibility of hosting a chronic GVHD website as a centralized resource for patients.

Other resources for patients and survivors

As described earlier, a number of resources are currently available for families dealing with the prospect of HCT in addition to survivors.

BMT InfoNet

BMT InfoNet provides online resources for patients during all phases of treatment:

- *Transplant center directory* (http://bmtinfonet.org/transplantcenters): an online directory of transplant programs in the United States and Canada providing detailed information on each program, including the medical director and key medical personnel; whether or not the center is accredited by the Foundation for Accreditation of Cellular Therapy and/or is an affiliate of the NMDP; the number of transplants performed, by type, in each of the three previous years; patient age and donor match criteria; and contact information. Patients can search the database by name of center, state, diagnosis, and age of patient (pediatric or adult). Data posted are provided directly to BMT InfoNet from each transplant center and are updated annually.
- *BMT InfoNet books* (http://bmtinfonet.org/products/books): access to patient handbooks about HCT and being a caregiver, and a calendar featuring transplant survivors, including one patient guide about HCT in Spanish.
- *Survivorship forum DVD*: videotaped presentations and slides from BMT InfoNet's Celebrating a Second Chance at Life Survivorship Conference.
- *Caring Connections Program* (http://bmtinfonet.org/services/support): a moderated peer support program linking patients with survivors who can provide emotional support.
- *Resource directory* (http://bmtinfonet.org/resources): a list of organizations that provide disease-specific information and financial support to HCT patients.
- *E-newsletter*: an electronic bulletin with information of interest to patients.
- *Help-line* (http://bmtinfonet.org/services/contactus): a service enabling patients to pose questions to a panel of medical experts.
- *Survivorship forums*: regional conferences to educate patients and survivors.
- *Attorney referral service*: for patients having difficulty securing insurance approval for their transplant or related treatment.
- *Directory of drugs used during transplant* (http://bmtinfonet.org/drugs): describes the purpose of the drug in the transplant setting, and potential side effects grouped by likelihood of occurrence.

In addition, patients in the United States can telephone toll free 888-597-7674 for personalized help with any of the above services.

Be the Match/National Marrow Donor Program

Be the Match provides resources for patients undergoing an HCT with an unrelated donor, some of which are also appropriate for patients transplanted with a related donor or undergoing an autologous transplant:

- Information about the donor search and HCT process.
- *Transplant center directory*: this details the cost of HCT with an unrelated donor at transplant programs in the United States, and also medical personnel at each center, the number of transplants performed for specific diseases, raw and risk-adjusted survival rates, and contact information.
- *DVDs*: for special-interest groups including young adults, pediatric patients, and older patients.
- *List of cord blood banks*: including contact information and criteria for donating cord blood.
- *Financial guide*: a workbook to help patients organize their finances.
- *Survivorship newsletter*: discussing some of the issues that survivors face from 3 months to 2 years after transplant.

Some of the online information is available in Spanish and other languages. Be the Match's Office of Patient Advocacy (OPA) provides telephone counseling for patients undergoing HCT with an unrelated donor, including help with tracking donor searches and research on disease- and treatment-related topics.

National BMT-Link (www.nbmtlink.org)

Offers a guide for HCT caregivers, a DVD entitled *The New Normal*, and a peer support program for HCT patients. Periodic teleconferences and an in-person support group for Michigan residents are also offered.

Center for International Blood and Marrow Transplant Research

The Center provides consensus guidelines on long-term follow-up care for patients after HCT (http://www.cibmtr.org/ReferenceCenter/Patient/Guidelines/pages/index.aspx). Recommendations are outlined for 6-month, 1-year, and subsequent annual check-ups. A separate version is available for patients and physicians. The information can be downloaded, or hard copies can be ordered.

The Children's Oncology Group

The Children's Oncology Group (www.survivorshipguidelines.org) provides long-term follow-up guidelines for pediatric cancer survivors.

National Institutes of Health

Sponsored Clinical Trials (http://clinicaltrials.gov) lists federally supported clinical trials with separate descriptions available for healthcare professionals and the lay public. Included are enrollment criteria, contact information for principal investigators, and a brief description of the trial's objectives.

The *Clinical Center* (http://clinicalcenter.nih.gov) in Bethesda, MD, provides free clinical care to patients who qualify for one of their clinical trials. Protocols for some HCT patients are available.

Other resources

- The *Children's Hospital Oakland Research Institute* (www.chori.org) offers free cord blood banking for families who have a child with a disease that is treatable by HCT.
- *Private HLA typing* (www.bonemarrowtest.com) to determine whether a person is a potential donor for a family member is sometimes requested by a physician without providing guidance to the potential donor on how to be tested. Some DNA laboratories provide this service only through a contract with a medical facility. Kashi Clinical Laboratories will arrange the service directly with the potential donor and provides necessary testing supplies and results via mail.
- *Disease-specific information and fundraising* or financial assistance for HCT patients is provided by a number of organizations. A list of such groups is maintained by BMT InfoNet (http://bmtinfonet.org/resources).
- The *ACOR* (www.acor.org) provides information about various diagnoses and treatment options, in addition to list-servs where patients and survivors can connect. The HCT group (BMT-Talk) and GVHD group are both very active and supportive lists.
- *BMT-Support* (www.bmtsupport.org) offers a real-time online chat room each week for HCT patients and caregivers. The chat is moderated by an HCT survivor with a nursing background.

Conclusion

Undergoing HCT is a very difficult experience both physically and emotionally. Working with a compassionate medical team that is attuned not only to the patient's physical needs, but also to his or her emotional needs, is a blessing that all patients will deeply appreciate. Being fully armed with information about long-term quality of life issues will help make the HCT patient's transition from being a successful patient to a successful survivor much easier.

Transplant physicians need not be the sole source of information for patients and survivors. Directing patients to resources outside the transplant program's area of expertise, such as experts in fertility, sexuality, cognitive retraining, fatigue management, and psychosocial support, will expand a patient's support network and enhance the likelihood that the survivor and his or her family will live well, even in spite of ongoing medical concerns.

Although HCT creates enormous challenges for patients and their loved ones, many survivors find personal growth in the experience. When asked what he would advise patients about to go through transplant, Steve Dugan, a 4-year survivor of an allogeneic HCT, offered this advice:

> **Expect** to be amazed by how much strength you find in yourself.
> **Expect** the shock of what's happening to you to continue for some time. Stolid acceptance of your situation is just not realistic.
> **Expect** to feel very alone and, at times, even detached from your surroundings.
> **Expect** to be shown, by the person closest to you, what love really means – maybe for the first time in your life. For me, that was, and always will be, my wife and best friend, Joyce. In Greg Allman's words: "When life's game gets so hard, I hold the highest card – the Queen of Hearts." That's Joyce!
> **Expect** there to be days when you say to yourself, "I just can't do this any more."
> **Expect** to make outrageous promises to God in exchange for clemency.
> **Expect** to find a whole new group of heroes – nurses.
> **Expect** your real friends to show up. Be prepared for surprises – both good and bad.
> **Expect** to be truly shaken – and, at times, depressed, by your physical appearance. Just remember: the mirror reflects what you look like – not who you are.
> **Expect** to catch yourself sometimes staring at your children, not wanting to miss a single breath they take.

But most importantly:

> **Expect** and believe that some day soon you will look at this whole episode of your life – in the rearview mirror.

Kathleen Jones, who underwent two HCTs after being diagnosed with chronic myeloid leukemia, summarizes a perspective shared by many survivors:

> The bone marrow transplants affected my life in every way. I am thankful to wake up every morning. I have learned compassion and empathy for those unable to be normal. I have learned not to spend time worrying about little unimportant things. I have learned to appreciate sunrises and sunsets. I have learned what it means when others are kind. I have learned the value of my family in my life, and just how precious life is, and how much I want to live it.

CHAPTER 36

Hematopoietic Cell Procurement, Processing, and Transplantation: Standards, Accreditation, and Regulation

Phyllis I. Warkentin[1] and Elizabeth J. Shpall[2]

[1] Foundation for the Accreditation of Cellular Therapy (FACT), University of Nebraska Medical Center, Omaha, NE, USA
[2] Department of Stem Cell Transplantation and Cellular Therapy, Division of Cancer Medicine, The University of Texas M.D. Anderson Cancer Center, Houston, TX, USA

Introduction

Hematopoietic cell transplantation (HCT) is established therapy for many serious congenital and acquired diseases of hematopoietic origin, including many high-risk malignancies. Hematopoietic cells (HCs) obtained from bone marrow, peripheral blood, and placental and umbilical cord blood cells are common graft sources derived from autologous, related, or unrelated donors. HCs are also used for functions other than as progenitor cells, such as post-transplant donor lymphocyte infusion [1]. Recent advances have expanded the range of patients who can successfully be treated using cord blood transplantation [2,3]. Cellular therapies have also expanded beyond hematopoietic and immunologic reconstitution to regenerative cellular interventions and new therapies using mesenchymal stem cells, dendritic cells, and gene-modified and other cells [4]. Rapid evolution of such therapies has heightened concern about the safety, purity, potency, and efficacy of these cellular products.

Governmental regulation

Governmental oversight of cellular therapies in the United States is based upon the Public Health Services (PHS) Act, the Federal Food, Drug, and Cosmetic Act (FFDC), and the Stem Cell Therapeutic and Research Acts of 2005 and 2010. Under the authority of the PHS and FFDC Acts, the Food and Drug Administration (FDA) is empowered to enact binding legislation related to cellular therapy products. Under the Stem Cell Acts, the Health Resources and Services Administration (HRSA) of the U.S. Department of Health and Human Services (HHS) oversees the several components of the C.W. Bill Young Transplantation Program and the National Cord Blood Inventory. Worldwide, blood and marrow stem cells are frequently transported across international borders to reach intended recipients. Each individual country has its own national and regional regulations. The FDA collaborates with foreign regulatory authorities to harmonize regulatory requirements and minimize the regulatory burden.

Role of the FDA

In 1997, the FDA published its unified and tiered approach to the regulation of traditional and new human cells, tissues, and cellular and tissue-based products (HCT/Ps) intended to provide regulatory uniformity and only the amount of regulation necessary to protect the public health [5]. Products expected to be at a higher risk for disease transmission or for contamination during collection or processing, such as allogeneic cells or cells highly manipulated ex vivo, are subject to more regulation than those products with less risk, such as autologous or minimally manipulated products. These FDA regulations are based on five public health and regulatory concerns: (1) prevention of transmission of communicable disease; (2) assurance that necessary processing controls exist to prevent contamination and to preserve the integrity and function of cells and tissues; (3) assurance of clinical safety and effectiveness; (4) assurance of necessary product labeling, including permissible promotion for proper product use; and (5) establishment of a mechanism for the FDA to communicate with the cell and tissue industry. A Tissue Reference Group, comprised of representatives of the Center for Biologics Evaluation and Research and the Center for Devices and Radiological Health, was established to provide a single reference point within the FDA for all regulatory questions about HCT/Ps. Recent decisions of the Tissue Reference Group have defined the appropriate regulatory pathway for specific products.

FDA regulations for cellular therapies are defined in Part 1271 of Chapter 21 of the Code of Federal Regulations (21 CFR 1271) that became effective May 25, 2005 [6–8]. This regulation establishes a uniform system for registration of manufacturers of HCT/Ps including HCs, delineates donor eligibility criteria, and describes current good tissue practices to prevent the introduction, transmission, and spread of communicable diseases [7,8]. HCT/Ps that meet the criteria listed below are regulated solely under the PHS Act, Section 361.

1. The product is minimally manipulated.
2. The product is intended for homologous use only, as reflected by the labeling, advertising or other indications of the manufacturer's objective intent.
3. The product does not involve combination of the cells or tissue with another article (excepting water, crystalloid, or sterilizing, preserving or storage agent).

4 The product does not have a systemic effect and is not dependent upon the metabolic activity of living cells for its primary function (unless autologous, first- or second-degree relative donor or for reproductive use) [6].

Other HCT/Ps, including unrelated donor allogeneic hematopoietic stem/progenitor cells, are regulated additionally as "biologic products" under PHS Act Section 351, current Good Manufacturing Practices, Quality Systems Regulations, and other portions of CFR, Chapter 21. These products are more than minimally manipulated (undergo processing that alters the biological characteristics of the cells), are used for other than their normal function, are combined with non-tissue components, and/or have a systemic effect (including unrelated donor HC) or are dependent upon the metabolic activity of living cells (excluding those for autologous or first- or second-degree related recipients) [5].

Under 21 CFR 1271, any establishment that participates in the manufacture of HCT/Ps must register with the FDA initially and annually, and maintain an updated list of HCT/Ps at least every 6 months.

Subpart C requires HCT/P facilities to screen and test cell and tissue donors for risk factors for, and clinical evidence of, relevant communicable disease agents or disease. Donor screening is the review of relevant medical records for indications of past or present infection and for risk factors for a relevant communicable disease. Donor testing is performing laboratory tests on a specimen, generally a blood specimen, collected from the donor to determine if she or he has been exposed to or infected with a relevant communicable disease or its agent. Testing must be performed by a laboratory certified to perform such testing on human specimens under the Clinical Laboratory Improvement Amendments of 1988 (42 U.S.C. 263a) and 42 CFR Part 493 (or equivalent) using appropriate FDA-licensed, approved, or cleared donor screening tests in accordance with manufacturer's instructions. Criteria for a relevant communicable disease are: (1) the disease agent is potentially transmissible by the HCT/P; (2) the disease agent or disease is sufficiently prevalent to affect the potential donor population; (3) the disease is potentially life-threatening or extremely serious; and (4) appropriate screening measures and/or testing assays are available. For allogeneic donors of HCs (including viable leukocyte-rich products), relevant communicable diseases and agents as defined in 21 CFR 1271 include at least: human immunodeficiency virus type 1 and type 2, human T-lymphotrophic virus type I and type II, hepatitis B virus, hepatitis C virus, *Treponema pallidum*, and human transmissible spongiform encephalopathy, including Creutzfeldt–Jakob disease [9–11]. Additional diseases/disease agents subsequently identified as relevant communicable diseases requiring donor screening are: West Nile virus, sepsis, vaccinia, and *Trypanosoma cruzi* (Chagas disease agent) [12–14]. An interorganizational Cellular Therapies Task Force has developed a Donor History Questionnaire, User Instructions, and supporting informational materials to screen hematopoietic progenitor cell (HPC) donors for communicable disease risk factors in accordance with these requirements. These materials are updated regularly and are available on organizational websites.

The current good tissue practice (cGTP) regulations are intended to ensure that products do not contain relevant communicable disease agents, are not contaminated or become contaminated during manufacturing, and that the function and integrity of products are not impaired through improper processing [6]. These GTP regulations include the requirements for an adequate organizational structure, sufficient personnel, and the establishment and maintenance of a comprehensive Quality Management Program. The Quality Program is responsible: (1) to ensure procedures related to core GTP requirements are established and maintained and personnel are appropriately trained in these requirements; (2) to ensure compliance with standard operating procedures requirements; (3) to receive, investigate, evaluate, and document complaints; (4) to share information related to potential contamination of HCT/Ps or disease transmission; (5) to ensure that HCT/P deviations are investigated and trended, and corrective and preventive actions are taken; and (6) to periodically audit activities related to core requirements. Core GTPs include adequate facilities; equipment, supplies, and reagents; environmental control and monitoring; proper processing, including process change and process validation; proper labeling and labeling controls; storage at proper temperatures in a manner to prevent mix-ups, including quarantine storage; and procedures for receipt, predistribution shipment, and distribution of HCT/Ps. Facilities must also report adverse reactions and product deviations and maintain procedures for tracking the product from recipient to donor and from donor to recipient or ultimate disposition.

Subpart F of 21 CFR 1271 describes the Inspection and Enforcement provisions. FDA conducts onsite inspections at its discretion with or without prior notification to determine compliance with applicable regulations. Facilities found to be out of compliance with regulations are ordinarily required to document compliance; FDA may also issue an order for retention, recall, or destruction of an HCT/P, or cessation of manufacturing.

FDA periodically issues guidance documents under the provisions of Good Guidance Practices, delineated in the Code of Federal Regulations to describe the Agency's interpretation of a regulatory issue, or to clarify specific issues which have been misunderstood [15,16]. Several of these documents are of particular relevance [9,11,17,18]. Draft guidance may be published, wherein interested persons are invited to comment on the current Agency thinking related to issues in the manufacture of cellular therapy products [19].

Cord blood cells

FDA regulations apply to all unrelated cord blood transplants performed in the United States, regardless of the country of origin of the cord blood unit. Umbilical cord blood cells are HCT/Ps as defined in 21 CFR 1271.3(d), and these regulations, which encompass registration and listing, donor eligibility, and good tissue practices, apply. In addition, as of October 20, 2011, unrelated donor, minimally manipulated cord blood is regulated as a biologic drug, requiring a biologics license application (BLA) for products intended for hematopoietic reconstitution for specified indications. The licensure process invokes additional regulations [20]. Licensed cord blood units meet all specifications in the licensure guidance and in the license application, including but not limited to description and characterization of the cord blood unit (safety, purity, potency, and identity), facility description, and validated manufacturing methods (including collection, processing, storage, selection, shipping and handling). To date, a few cord blood banks have achieved licensure; other applications are in progress.

Continued availability of unlicensed cord blood units is essential to ensure diversity of HLA phenotypes and access to transplantation for individuals with less common HLA types. Unlicensed cord blood units are available for transplantation under an approved Investigational New Drug (IND) application. The IND may be held by a cord blood bank, by a physician or transplant center, or by a national or international registry involved in coordinating the distribution of cord blood units, or by another sponsor [21]. Cord blood units obtained from ineligible donors and distributed via the IND mechanism require documentation of urgent medical need as defined in 21 CFR 1271.60. The National Marrow Donor Program holds an IND for the distribution of unlicensed, minimally manipulated, unrelated allogeneic cord blood units intended for hematopoietic reconstitution for specified indications. Unlicensed cord blood units may also be available through a separate treatment IND for patients with other serious conditions who lack therapeutic alternatives.

State regulation

Governmental regulation of HC therapy at the state level is fragmented. Some states have adopted mechanisms of qualifying HCT programs and facilities, such as certificate of need process or licensure. Some states, such as New York, have adopted specific regulations for processing of and storage facilities for HCT/Ps [22,23]. Other states require accreditation by a professional organization. Currently, Massachusetts and Maryland require accreditation by the Foundation for the Accreditation of Cellular Therapy (FACT) to perform HCT within those states. Many US states have little specific regulation.

Stem cell Acts

The Stem Cell Therapeutic and Research Act of 2005 and the Stem Cell Therapeutic and Research Reauthorization Act of 2010 authorize the C.W. Bill Young Cell Transplantation Program and the National Cord Blood Inventory, managed by the Health Resources and Services Administration (HRSA). The overall goal of the Stem Cell Acts is to increase access to unrelated donor transplantation and improve transplant outcomes. The Advisory Council on Blood Stem Cell Transplantation provides expert recommendations to the Secretary of Human and Health Services on advances in stem cell transplantation and the activities of both the Program and the National Cord Blood Inventory (NCBI), including the designation of the entities to provide accreditation for participating cord blood banks.

There are four major components to the C.W. Bill Young Transplantation Program. Three components are managed by the National Marrow Donor Program (NMDP): The Office of Patient Advocacy/Single Point of Access and the Coordinating Centers for Bone Marrow and Cord Blood. The fourth component, the Stem Cell Therapeutic Outcomes Database (SCTOD), is operated by the Center for International Blood and Marrow Transplant Research (CIBMTR), and requires reporting of all related and unrelated donor allogeneic HCT performed in the United States or performed using products procured from the United States. Created in 2004, CIBMTR is a partnership between the research arm of the NMDP and the International Bone Marrow Transplant Registry. Its expertise is in collecting and managing data, working with transplant centers and regulatory agencies, histocompatibility and bioinformatics, and in creating and managing research sample repositories. The SCTOD allows analysis of diagnoses for which transplant may be an option, novel therapeutic uses of HCs, transplant preparative regimens and procedures, transplant center-specific patient outcomes, patient access to HCT, quality of life, and donor registry and cord blood inventory size and adequacy.

The National Cord Blood Inventory (NCBI) provides some funding to selected cord blood banks for the collection and storage of at least 150,000 cord blood units to be available to treat patients who may need an unrelated donor graft. Goals of the NCBI are to encourage cord blood donation, particularly among racially or ethnically diverse populations, to collect and store units in designated cord blood banks, to ensure appropriate consent and confidentiality, and to provide cord blood unit data to the SCTOD. Thirteen US cord blood banks currently participate in this effort.

Voluntary professional accreditation

Foundation for the Accreditation of Cellular Therapy (FACT)

Historical background

FACT is non-profit organization affiliated with the University of Nebraska Medical Center, Omaha, Nebraska that was cofounded in 1995 by the International Society for Cellular Therapy (ISCT) and the American Society for Blood and Marrow Transplantation (ASBMT) to promote quality patient care and laboratory practice in HCT through the establishment of comprehensive professional standards and implementation of its voluntary accreditation program for the procurement, processing, and transplantation of HC products [24,25]. FACT was initially founded as the Foundation for the Accreditation of Hematopoietic Cell Therapy (FAHCT). The name was changed in December 2001 to encompass, in addition to HC products and therapies, the new and exciting therapies using mesenchymal stem cells, dendritic cells, targeted lymphocytes, genetically modified cells, pancreatic islets, and others.

ISCT was formed in 1992 as a professional society of scientists and physicians working in HC manipulation. Its membership includes most of the major HCT programs worldwide. The Regulatory Affairs Committee of ISCT developed the first draft of Standards for Hematopoietic Cell Collection and Processing in 1994. The other parent society of FACT, ASBMT was formed in 1993 as a professional society of physicians and investigators involved in the clinical conduct of HCT. The ASBMT Clinical Affairs Committee developed the first Clinical Standards for Hematopoietic Cell Transplantation. Believing that quality care can only be achieved if both clinical and laboratory issues are addressed, these laboratory and clinical standards were merged to form the basis for the first edition of FAHCT's *Standards for Hematopoietic Progenitor Cell Collection, Processing and Transplantation*, published in 1996 [26]. These Standards were unique in breadth and depth, applicable to all phases of the collection, processing, storage, and administration of hematopoietic progenitor cells (HPCs) regardless of tissue source (bone marrow, umbilical cord blood, peripheral blood, or other tissue source); and to "therapeutic cells," nucleated cells collected for use other than as HPCs. Standards define an infrastructure required for the safe and efficacious collection, processing, storage, and use of HCs; define the minimum education and experience necessary for staff; and require an ongoing assessment of patient outcome, including neutrophil and platelet engraftment and 100-day and one-year morbidity and mortality.

A companion accreditation manual was published to provide guidance to applicant facilities and personnel and to FACT inspectors [27]. Based upon this first edition of standards, the FACT accreditation program was initiated in 1996. The first on-site inspections were performed in 1997; and the first US HCT accreditations were awarded in March 1998.

In 1997, representatives of FACT, ISCT, and ASBMT collaborated with members of The International NetCord Foundation, an independent association of cord blood banks, to draft additional standards to cover the complexity of cord blood banking. The first edition of NetCord–FACT *International Standards for Cord Blood Collection, Processing, Testing, Banking, Selection, and Release* was developed by consensus of international experts in the field, initially published in June 2000, and revised in 2002 [28]. NetCord–FACT Standards superseded all cord blood standards in FAHCT *Standards for Hematopoietic Progenitor Cell Collection, Processing, and Transplantation*, excepting those clinical standards related to the transplantation of cord blood cells.

These comprehensive standards apply to both unrelated donor cord blood units and units collected and stored for a specific family or designated recipient. A key concept is that the accredited cord blood bank is responsible for all phases of donor recruitment, screening, and testing, and for product collection, transport, processing, storage, and release for clinical use [29]. These Standards form the basis for the voluntary accreditation of cord blood banks worldwide. The first cord blood banks achieved FACT–NetCord accreditation in 2004.

FACT representatives worked with colleagues from the European Group for Blood and Marrow Transplantation (EBMT) and ISCT-Europe to establish the Joint Accreditation Committee of ISCT-Europe and EBMT (JACIE) [30]. JACIE adopted the first edition of the FAHCT Standards in 1999 [31]. The second edition of the Standards was jointly reviewed by FACT and JACIE; subsequent editions have been jointly developed and entitled *FACT–JACIE International Standards for Cellular Therapy Product Collection, Processing, and Administration* [32]. The primary aim of JACIE is to improve the quality of HCT in Europe through its accreditation and education programs, and to work toward international harmonization of standards and regulations.

Based on the FACT model, the JACIE accreditation program was fully implemented in January 2004 with initial support from the European Union under the Public Health Programme (2003–2008). During this process, JACIE inspectors and staff found that almost all centers were functioning at a high level of excellence, with the majority having only minor deficiencies noted at the on-site inspection. When formally surveyed, these centers reported that implementation of JACIE accreditation required a significant investment of time and resources, but all believed that the result was a demonstrable improvement in the accredited program [33]. Recently, the impact of the JACIE quality management system was assessed among the 421 transplant teams in Europe [34,35]. Patient outcome after allogeneic transplant was systematically better when the transplantation center was at a more advanced phase of JACIE accreditation, independent of the year of transplantation and other risk factors. Improvement was assessed by relapse-free survival, comparing each center against itself during four periods of time: pre-application for accreditation, preparation for accreditation, application, and accredited. This approach was possible because centers in Europe did not embark on the JACIE accreditation process at the same time. A similar trend toward improved survival was also seen among autologous transplant recipients. Additional information and documents are available on the JACIE website (www.jacie.org).

Standards

All FACT Standards are developed by consensus of world-renowned experts active in cellular therapy. Development includes discussion with representatives of regulatory bodies and legal review. Standards are based on established evidence from the medical literature whenever possible, incorporate sound recommendations that foster quality medical and laboratory practice; and have maintained their unparalleled depth and breadth through subsequent revisions. All Standards require compliance with applicable law, but may exceed minimum regulatory requirements.

An international oversight committee is responsible for each edition of Standards. An overall Standards Committee Chairperson is appointed by the FACT Board of Directors for a term to encompass the development and publication of one edition of each set of standards, cellular therapy and cord blood banking. Each edition is published for comment by members of the cellular therapy community and the public. Each comment is reviewed, and incorporated as appropriate.

FACT–JACIE International Standards for Hematopoietic Cellular Therapy Product Collection, Processing, and Administration

Cellular Therapy Standards, now in the sixth edition, are designed to provide minimum guidelines for facilities and individuals performing HCT and related cellular therapies [32]. Central to the Standards is the requirement that all clinical, collection, and processing facilities develop and maintain a comprehensive Quality Management Plan that includes at least the following components: defined organizational structure; personnel requirements including qualifications and training; process and procedure development and document control; agreements; outcome analysis and product efficacy; audits; management of errors, accidents, complaints, and adverse events, including management of products with positive microbial culture results; product tracking; and, where appropriate, validation and/or qualification of critical procedures, reagents, supplies, equipment, and facilities [36,37]. The current edition also includes many of the regulatory requirements from the United States FDA and the Directives of the European Union [6,38–40]. Cellular therapy product proper names are defined as the official terminology of *ISBT 128* [41,42].

Standards for each participating service or facility in the cellular therapy program require minimum procedure volumes and leadership experience, adequate facilities, specific content and format for standard operating procedures, and specific personnel. Participating services are required to maintain active communication with each other. Histocompatibility testing must be performed according to currently accepted standards and protocols by a laboratory accredited by the American Society for Histocompatibility and Immunogenetics, the European Federation for Immunogenetics, or an accrediting body providing equivalent services. All other laboratory testing must be performed by laboratories appropriately licensed and/or accredited for the specific assays.

Clinical standards define a blood and marrow transplant program as an integrated medical team housed in a defined location, with a Clinical Program Director(s) and common staff training programs, protocols, and quality management systems that use HC collection and processing facilities that meet FACT–JACIE Standards. Clinical standards enumerate support and consultative staff; cover donor evaluation, selection, eligibility, and consents; provide minimum guidelines for cellular therapy product administration, including the preparative regimen of high-dose therapy; describe the appropriate management of clinical research and Institutional Review Board-approved protocols; require maintenance of complete and accurate records; and require outcome analysis of both individual patients and aggregate data.

Cell collection standards define elements common to both bone marrow- and apheresis-derived peripheral blood HCs, and detail those requirements unique to each cell source. Comprehensive laboratory standards detail requirements for personnel; process controls; inventory management; validation and qualification of facilities, supplies, reagents and equipment; labels and labeling; storage; transport; and records. The intent is to establish that the laboratory is operated in a responsible and responsive manner, and that deviations in processes or products are documented, investigated, and appropriately communicated to the clinical team. Laboratory and collection personnel are expected to follow clinical outcome as one measure of product safety and efficacy.

Notable changes in the sixth edition of the HPC Standards include,

1. Change in the title to add Hematopoietic, to define the scope of these requirements, particularly for the increasing number of accredited facilities that also support non-hematopoietic cellular therapies. FACT has published a separate set of Standards (the "Common Standards for Cellular Therapy") applicable to non-hematopoietic indications; however, the current Hematopoietic Standards are all-inclusive. Facilities pursuing accreditation for hematopoietic services in addition to other specialties may consult these Hematopoietic Standards as a single reference.
2. Revision in the definition of a single clinical program to remove the requirement for geographic proximity, but retain the intent that all clinical sites within a single program demonstrate regular interaction. Advances in technology have enabled clinical sites across greater distances to cohesively interact.
3. Increased emphasis on outcomes and outcome analysis. Outcome of HPC therapy must include individual product / patient data and aggregate data for each type of product or recipient type. For HPC products intended for hematopoietic reconstitution, review of outcomes must include acute and chronic graft versus host disease and central venous catheter infection, in addition to engraftment and overall and treatment-related mortality at 100 days and one year as required in the fifth edition. Further, the Clinical Program should achieve one-year survival outcome within or above the expected range when compared to published data. For US programs, this is intended to utilize CIBMTR Transplant Center-Specific Outcome Data at a minimum. If the expected one-year survival outcome is not achieved, the accredited Clinical Program will be required to submit a corrective action plan that includes investigation of the causes for less than expected survival and process improvement aimed at correction of those issues. Programs are expected to also assess other relevant outcome measures.
4. Definition of minimum amount of annual continuing education as ten hours per year for physicians, advanced practice professionals, pharmacists, and quality manager. Appropriate subject matter is also defined.
5. Addition of specific requirements for pharmacists and physicians-in-training who participate in clinical care.
6. Programs must be actively implementing ISBT 128 technology in addition to use of standard terminology. Previously, a plan to implement ISBT 128 was required.
7. Specific procedures are required for administration of ABO-incompatible products, including indications for red cell and/or plasma reduction. Additionally, this topic is a new requirement for attending physician education and competency.
8. For cord blood units, programs must have defined procedures to verify unit identity.
9. Informed consent and donor evaluation by a health care provider who is not the primary provider for the recipient is now required rather than recommended [43–45].
10. Pregnancy test rather than only assessment is required.
11. Clinical programs must have a policy for anti-HLA antibody testing in mismatched donors.
12. Histocompatibility laboratory accreditation broadened slightly, to allow demonstrable equivalence.
13. Clinical programs must utilize appropriately accredited laboratories for chimerism testing.
14. Numerous changes were made in quality management requirements, including strengthening the requirements for document control, annual reporting, and deviation investigation and resolution.

The Accreditation Manual has been updated to utilize increasingly universal language and to include governmental regulations of the European Union, the Australian Therapeutics Goods Administration, and others. FACT–JACIE Standards and the accompanying accreditation guidance manual are available in print and online at the FACT website (www.factwebsite.org).

The Accreditation Manual has been updated to utilize increasingly universal language and to include governmental regulations of the European Union, the Australian Therapeutics Goods Administration, and others. Guidance material is organized to include the standard, followed by Explanation, Evidence (documents that may be requested or provided as documentation of compliance), and Examples (specific processes that would be considered to be compliant with the Standards). FACT–JACIE Standards and the accompanying accreditation guidance manual are available in print and online at the FACT website (www.factwebsite.org).

NetCord–FACT International Standards for Cord Blood Collection, Processing, Testing, Banking, Selection, and Release

These Standards are intended for the field of cord blood banking, in which a cord blood bank is defined as an integrated team responsible for the collection, processing, testing, banking, selection, and release of cord blood units, either for unrelated donor use or restricted for use by a specific donor family [29]. There are some differences between Standards for family units and Standards for unrelated donor units, and in the methodologies employed to meet these Standards, particularly in the relationships among the bank, the cord blood unit collector, the donor, and the collection facility. However, in either case, Standards are inclusive of all processes from donor recruitment through distribution for administration. Most processing standards are similar due to the importance of adequate numbers and viability of cells.

Cord Blood Bank Standards require that each cord blood bank establish and maintain a comprehensive quality management program. The bank staff is required to follow clinical outcomes from each unit released for transplant in sufficient detail to ensure that the procedures in use continuously provide a safe and effective product, and to assess aggregate data as part of a stability program designed to determine the appropriate expiration date for cryopreserved units. Comprehensive processing, storage, and labeling standards are consistent with *ISBT 128* terminology and labeling requirements [41,42].

An Accreditation Manual accompanies the Cord Blood Standards and provides Explanation, Evidence (documents that may be requested or provided as documentation of compliance), and Examples (specific processes that would be considered to be compliant with the standards), similar to the Cellular Therapy Accreditation Manual [46]. Standards and guidance manual are available in print and online at the FACT website (www.factwebsite.org).

Accreditation process

The goal of the voluntary inspection and accreditation is to improve the quality of care at each transplant center in the expectation that these improvements will lead to improvement in patient outcomes. Multiple levels of review and oversight ensure accreditation is consistently awarded based upon documented compliance with the published international standards as assessed through submitted documents and a rigorous and comprehensive on-site inspection. The process is conducted in a collegial and collaborative manner among peers, and is designed to accommodate various practices that are compliant with the Standards. All inspectors are volunteers

Table 36.1 Foundation for the Accreditation of Cellular Therapy (FACT) Inspector Qualifications

Hematopoietic Cell Therapy Inspector
- Individual member of ISCT, ASBMT, or American Society for Apheresis (ASFA)
- Affiliated with a FACT-accredited program
- Meets all educational and experience requirements
- Attended a FACT training course; passed written exam over current Standards and accreditation processes, and successfully completed inspection as a trainee
- Documented competency on FACTWeb
- Maintains current statements of compliance with confidentiality, duality of interest, and other policies
- Participates in at least one FACT continuing education event annually

Clinical Program Inspector
- Is a licensed physician
- Has at least 2 years' experience in hematopoietic cell transplantation

Apheresis Collection Inspector
- Has a relevant doctoral, nursing, or biological science degree
- Has completed formal training in apheresis or has at least 1 years' experience in peripheral blood progenitor cell collection by apheresis as a director, medical director, physician, supervisor, or assistant supervisor

Cell Processing Facility Inspector
- Has relevant doctoral or biological science degree
- Has at least 2 years' experience as director, medical director, or supervisor of a cell processing laboratory

Processing Facility with More than Minimal Manipulation Inspector
- Processing Facility Inspector qualifications plus
- Has experience processing hematopoietic-derived cells with more than minimal manipulation under IND

Cord Blood Bank Inspector
- Individual member of ISCT, ASBMT, ASFA, ISCT-Europe, or NetCord
- Affiliated with a FACT or JACIE accredited hematopoietic cell therapy program or FACT–NetCord accredited or applicant cord blood bank
- Meets all educational and experience requirements
- Has attended FACT–NetCord training course, passed a written exam over the current CBB Standards and processes, and successfully completed inspection as a trainee
- Maintains current statements of compliance with confidentiality, duality of interest, and other agreements
- Participates in at least one FACT continuing education event annually

Cord Blood Collection Inspector
- Has a relevant doctoral, nursing, or biological science degree
- Has at least 1 years' experience as a collection supervisor in a cord blood bank, or is an active FACT or JACIE clinical or collection inspector

Cord Blood Laboratory Inspector
- Has a relevant doctoral or biological science degree
- Has at least 1 years' experience as director, medical director, or supervisor of a cord blood bank laboratory or hematopoietic progenitor cell processing laboratory

active in the HC therapy field, and meet the minimum qualifications as listed in Table 36.1.

FACT accreditation in HCT is focused on the clinical program, which must perform the minimum number of transplants per year, and must use cell collection and cell processing facilities that also meet FACT–JACIE Standards. A collection and/or processing service may be an integral part of a clinical program, or may be accredited to provide these services by contract to one or more clinical programs. No specific structure is required; however, each collection or processing facility must have a minimal level of experience prior to accreditation. Mechanisms have been defined for new facilities to be initiated while accreditation is maintained.

In response to inquiries, FACT now offers a specific accreditation for collection facilities that perform marrow and/or peripheral blood cellular therapy product collection by apheresis for products under IND or licensure, intended for further manufacture. FACT supports responsible research in compliance with applicable laws and regulations, and offers its accreditation to those facilities collecting cell products for and distributing to entities following appropriate regulatory pathways. Facilities accredited under this pathway must fully disclose what processes are accredited by FACT in order to properly inform the public of the scope of their accreditation.

In addition, FACT now offers accreditation for cellular therapy product processing with more than minimal manipulation in an effort to increase quality practices throughout cellular therapy research. By encouraging facilities to meet minimum requirements for FACT accreditation, FACT contributes to a major goal of bringing promising therapies to patients. It is understood that some of FACT–JACIE Standards for processing are specific to HCs, and that there are inherent differences between research products and standard of care HCs. FACT–JACIE Standards can provide direction on meeting requirements of GMP and GTP regulations, and FACT accreditation provides external validation of regulatory compliance. Typically, these products require an IND application for clinical use. Where apparent discrepancies between FACT Standards and IND requirements exist, the quality requirements for planned deviations provide a path forward. Inspectors for these programs are knowledgeable and experienced with the intricacies of INDs, and are motivated to advance the quality of research and not to restrict it. While some of these cellular therapy products may be used in the traditional transplant program and/or manufactured in the traditional cellular therapy laboratory, others will be utilized in areas of regenerative medicine and/or immunology and may require separate staffs and facilities for their manufacturing procedures. The outcome analysis of these newer products is often based in safety, with recommendation to attempt to assess efficacy as applicable. This is an important extension of standards and accreditation for the future.

Though international in scope, the FACT inspection and accreditation process is conducted in English and requires applicant organizations to translate some, but not all, documents. On-site translation, demonstration of compliance, and translated flow charts are some of the tools used in the on-site inspection, which is built upon trust that each participant endeavors to comply with Standards and achieve quality for patients.

The essential elements of FACT accreditation are an initial eligibility application, submission of required documents, an on-site inspection, review by an Accreditation Committee, correction of deficiencies, and fulfillment of all other requirements. The accreditation process has recently been converted to an electronic, web-based system, the FACTWeb Accreditation Portal. The FACTWeb portal was developed by the FACTWeb Oversight Committee comprised of Board members, volunteer inspectors, and representatives of each type of accredited organization. This oversight committee verified that all user needs were considered, that applicants and inspectors were appropriately trained, and that the process remains congruent with FACT's objectives. Following the initial launch of the portal in 2012 with implementation of the fifth edition of FACT–JACIE Standards, the committee turned its attention to continuous improvement in design, accessibility, and clarity.

The process for initial FACT accreditation of HCT is detailed below.

1 *Eligibility application.* A Program or Facility Director will register interest in accreditation for one or more of the transplant-related services using the online eligibility application. Required information includes demographics and a description of the services for which accreditation is sought. The FACT Accreditation Office staff will review this information, determine if the program or facility is eligible for accreditation, and will generate the customized compliance application specific to the applicant.
2 *Compliance application.* The compliance application is based on services provided by the applicant. Generally questions that do not apply to the specific program should not be present. Applicants will indicate compliance with each Standard, and upload documentation as required. Guidance related to each standard is readily available on the application to assist the applicant in completing

the application and uploading required documents. The compliance application also serves as a checklist for the inspector at the on-site inspection. Use of checklist documentation ensures that each program is measured against the Standards, and that the inspection will be complete. Completion and submission of the compliance application is expected within 12 months of its receipt for initial accreditation.

3 *Request for information.* Request for information (RFI) is a functionality used by the FACT coordinators and inspectors to communicate in real time with each other and/or the applicant to clarify information or request additional documentation.

4 *On-site inspection preparation.* The submitted materials are reviewed by a designated FACT Accreditation Coordinator. Observations are communicated electronically to the applicant, allowing time for additional submissions or corrections. The applicant indicates potential dates for the on-site inspection when all key personnel will be available.

The inspection team is selected from the available inspectorate based upon the size and complexity of the applicant program, assuring that members of the team have the training and experience necessary to assess all HCT activities. Inspectors may be replaced if the inspector or applicant perceives a potential conflict of interest. When the assignment has been confirmed, each member of the inspection team is given access to the applicant's on-line compliance application and all uploaded documents that serve to verify compliance with the Standards. The inspection team has 3–4 weeks to review the application and related documents, request additional information, and meet by teleconference to prepare for the inspection.

5 *On-site inspection.* The on-site inspection should be completed in 1 day, starting with introductions and ending with a summation of major observations, but not a final determination of accreditation status. Observations made at the on-site inspection are recorded electronically on the compliance application. A deficiency is any observation that does not comply with a mandatory requirement, stated in the Standards as "shall." A variance from recommendation is the failure to be in compliance with a standard stated as "should."

Within 2 weeks of the on-site inspection, each inspection team member will complete his/her report online, and the Team Leader will complete and submit the final report. Submitted reports are reviewed by the FACT Accreditation Coordinator, edited as required, and submitted to the Accreditation Committee.

6 *Accreditation Committee review.* Each applicant program is presented to the FACT Cellular Therapy Accreditation Committee by the Accreditation Coordinator who has worked with the applicant and the on-site inspection team. Each of the on-site inspectors is invited to join the Accreditation Committee call when a relevant program is being discussed to provide additional information as needed, and to learn the process and interpretations from seasoned inspectors and reviewers. The Accreditation Committee is chaired by the FACT Medical Director, and consists of the chairperson of the Standards Committee, active inspectors representing all three of the major areas (clinical, collection, and laboratory), and representatives of the FACT Board of Directors. The possible outcomes of Accreditation Committee review are listed in Table 36.2. The Board of Directors retains ultimate responsibility for these outcomes, handles any complaints or appeals, hears and decides contentious issues, and makes any precedent-setting decisions. The accreditation outcome is communicated via the FACTWeb portal to the Program Director and other designated personnel. This notification includes instructions for submitting responses or additional information necessary to complete the process and achieve accreditation. The Accreditation Committee members also contribute suggestions to improve the process.

Table 36.2 Foundation for the Accreditation of Cellular Therapy (FACT) potential accreditation outcomes

No deficiencies or variances	Full accreditation for 3 years granted as of the date of the Accreditation Committee meeting
Few or scattered deficiencies	Accreditation granted upon documentation of correction of deficiencies, with or without review of corrections by the Accreditation Committee
Significant systemic deficiencies; numerous repeat deficiencies	Requires documentation of correction of all deficiencies, then focused re-inspection of all or parts of a program. Accreditation is granted after successful completion of the re-inspection
Failure to meet eligibility requirements or to respond appropriately with documentation of correction of deficiencies	Non-accreditation. If circumstances change, resubmission of eligibility application required to restart the process

7 *Accreditation.* Accreditation is awarded after any deficiencies have been corrected and these corrections documented. The Accreditation Committee may review this documentation if needed. Accreditation is valid for 3 years. Accredited programs are announced in the newsletters of the ISCT and ASBMT, and listed on the FACT website.

8 *Annual report.* Each accredited program and facility reports annually on the number of autologous and allogeneic HCT patients treated in the previous 12 months, and on any significant changes in personnel, location, or complexity of service. In addition, programs may be asked to document compliance with specific Standards that are new or have been problematic.

9 *Accreditation renewal.* Programs are expected to have completed the renewal process prior to the expiration of the prior accreditation. One year prior to expiration of accreditation, each accredited program will receive notification to begin the application for renewal, which is essentially identical to initial accreditation. The applicable standards will be the edition that is current on the day of the on-site inspection.

10 *Cord blood banking.* The accreditation process for cord blood banks is identical to that for cellular therapy programs, except that the on-site inspection generally requires at least 2 full days. There is a separate Cord Blood Bank Accreditation Committee; and the Boards of Directors of FACT and NetCord maintain accountability for these accreditation decisions.

Currently, over 200 programs in North America, Australia, New Zealand, South America, and Asia have achieved and maintained accreditation. For North America, this represents an estimated 90% of eligible programs. Special recognition has been given to the over 90 programs continuously accredited for 10 or more years. Over 45 cord blood banks have been accredited worldwide. There are over 160 active FACT inspectors. The initial inspection summaries of the 145 programs or facilities inspected under the first edition of the FACT Standards (1996) were reviewed to determine the most frequently cited deficiencies and variances from recommendation. The results from the first 76 programs have been published [47]. Similar to the results observed by JACIE, the results of recent on-site FACT inspections demonstrate that most programs are functioning at a high level of quality and have addressed most of the Standards. Deficiencies observed

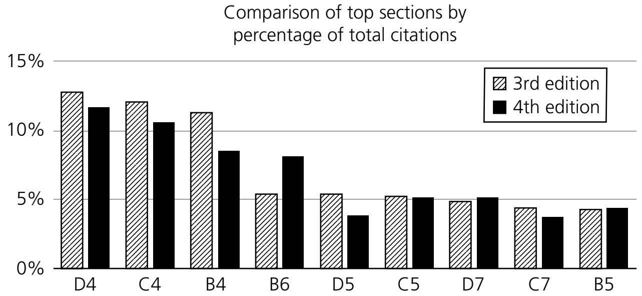

Figure 36.1 The top issues cited as deficiencies during FACT inspections based on the third and fourth editions of Standards, shown as percentage of the total. The Standards sections are: B4 – Clinical Quality Management; C4 – Collection Quality Management; D4 – Laboratory Processing Quality Management; B6 – Donor Selection, Evaluation, and Management; B5 – Clinical Policies and Procedures; C5 – Collection Policies and Procedures; D5 – Laboratory Processing Policies and Procedures; C7 – Collection Labeling; D7 – Laboratory Processing Labeling.

generally represent failure to completely address a Standard or to update practice based upon a new requirement in a new edition of Standards.

The most commonly observed deficiencies related to the third and fourth editions of FACT Standards are shown in Figure 36.1. The total numbers of deficiencies were decreased between the third and fourth editions, despite the increase in the total number of standards; however, the areas in which deficiencies are noted have remained constant. The top issues are Quality Management, Policies and Procedures; Donor Selection, Evaluation, and Management; and Labeling, cited across all areas of the HCT program. Deficiencies represented a failure to perform specific required activities, or failure to describe the ongoing quality activities in the QM plan. Standard operating procedures deficiencies included deficiencies both in format and content. Potential explanations for the continued frequency of these deficiencies include a large number of standards; new requirements in each edition of Standards, complex processes that include many concepts to be complete; and lack of attention to labeling process while completion of the label is simpler. In addition, inspectors have improved, both in their understanding of standards requirements and in the quality they expect to see in the applicant program.

Significance of FACT accreditation

FACT accreditation helps a cancer program attain its ranking among America's Best Hospitals, published by *U.S. News & World Report* [48]. Since April 2007, FACT accreditation for allogeneic HCT has been awarded one point toward best hospital status. FACT accreditation for autologous HCT only is awarded one half-point. In addition, *U.S. News & World Report* includes FACT accreditation as a factor in the selection of the top 10 America's Best Children's Hospitals [48].

FACT–JACIE Standards have achieved international acceptance, as best demonstrated by the joint authorship and committee membership in Standards development. In Australia, the Therapeutic GoodsAdministration has accepted the collection and laboratory standards as the regulation for the field. In the United States, cooperative groups require institutions entering patients on HCT trials to have FACT accreditation. Most insurance companies require HCT programs to disclose FACT accreditation status as part of the application for Center of Excellence designation.

Beginning in 2010, cellular therapy programs that have achieved 10 years of continuous accreditation are surveyed about the impact of FACT accreditation on their program and associated challenges. To date, respondents have unanimously agreed that FACT accreditation has positively impacted the quality within their programs. Peer perception, attitude of the affiliated institutions towards the program, insurance reimbursements, number of transplants performed, and participation in clinical trials were also identified as having been positively impacted. Challenges identified, including time and resources required to maintain accreditation, keeping current with the standards, and reviewing, revising, and organizing documents, provide valuable feedback to FACT in development of future educational opportunities, tips, and tools to assist programs in compliance. Peer to peer advising and a consulting service are newly launched initiatives based on the needs identified by applicant and accredited programs.

AABB

The AABB (formerly the American Association of Blood Banks) is an international professional society representing approximately 8000 individuals and 2000 institutions involved in blood banking, transfusion medicine, and cellular therapies [49]. The association includes physicians, nurses, medical technologists, administrators, scientists, and other healthcare providers committed to patient safety and optimizing donor care through its programs of voluntary standards, accreditation, and education. The AABB has a long history of standard-setting in blood and blood component collection, processing, storage, and transfusion, having published its first edition of *Standards for a Transfusion Service* in 1958. Since that time, AABB has expanded its repertoire of standards to include immunohematology reference laboratories, perioperative autologous blood collection and administration, relationship testing, molecular testing for red cell, platelet, and neutrophil antigens, and cellular therapy product services, including hematopoietic progenitor cells, somatic cells, and cord blood cells. In 2009, AABB formally established its Cellular Therapy Section within the association to provide leadership to the organization and its members; and in 2012, it launched its Center for Cellular Therapy to further serve cellular therapy professionals, to foster patient and donor safety, and to encourage responsible innovation in cellular therapy and regenerative medicine [49].

Standards

Originally published as separate volumes, AABB now publishes a single set of cellular therapy standards that encompass hematopoietic cells, somatic cells, and cord blood services [50]. AABB Standards are developed by expert volunteers; are revised biennially, and are based upon published literature, accepted good medical practice, principles of good manufacturing practices and quality assurance, applicable regulations, and the standards of other organizations. Internationally accepted quality management systems requirements are accompanied by technical requirements appropriate to the specific discipline. Although very different in structure, the content of the AABB Standards for Cellular Therapy Services is fundamentally consistent with the FACT–JACIE International Cell Therapy Standards.

Accreditation: The current edition of Standards and the Accreditation Information Manual that accompanies it form the basis for AABB accreditation. Accreditation is based upon submission of demographic information and an on-site inspection, coordinated by a paid, full-time quality assessor, and executed by volunteer assessors with relevant subject matter expertise who have been trained in auditing and assessing techniques. On-site assessments are loosely scheduled to occur within a specific 3-month period prior to the expiration of the prior accreditation; however, the exact dates are unannounced. The on-site assessors determine compliance or non-compliance with Standards, and leave a written report of non-conformities with the applicant organization at the end of the assessment. Accreditation is offered worldwide. Facilities may apply for variance if desired, especially due to US regulatory requirements that may not be applicable in other parts of the world. Accreditation is valid for 2 years.

Separate from its standard-setting and accreditation activities, AABB offers a consulting service in cellular therapy, educational and training materials for individual or institutional use; numerous publications, and an annual meeting. AABB participates in several inter-organizational and international activities that address prevention of transmission of infectious diseases, labeling, and development of the field of cellular therapy worldwide. With the growth of clinics and physicians using adult autologous cell therapy for a host of indications outside the traditional hematopoietic stem cell transplant setting, AABB announced in 2012, a collaboration with the International Cellular Medicine Society (ICMS) to develop standards and offer accreditation globally for these therapies [51].

National Marrow Donor Program

The National Marrow Donor Program (NMDP) was founded in 1987 as a cooperative effort of the AABB, the American Red Cross, the Council of Community Blood Centers, and the United States Navy to facilitate volunteer unrelated donor marrow transplantation. It comprises a network of cooperating facilities, including transplant centers, donor centers, marrow collection centers, apheresis centers, cord blood banks, recruitment groups, cooperative donor registries, contract laboratories, and cell and serum repositories. The Health Resources and Services Administration has regulatory authority over NMDP.

Since its inception, NMDP has established standards for membership participation. A Standards Committee composed of experts in various aspects of HCT is in place to provide continuous review and revision of these standards. NMDP Standards cover cells obtained from marrow, peripheral blood, and umbilical cord blood. The Standards include standards for participating centers and groups, personnel qualifications, required support services, policy and procedure requirements, confidentiality, recruitment of the unrelated donor, donor medical and laboratory screening and testing, informed consent, donation and transplant process, a few collection, packaging, labeling, and processing standards, and records requirements. Standards for laboratory processing are less detailed than those of FACT–JACIE, NetCord–FACT or AABB, since most of the product processing is performed by laboratories integral to the recipient's transplant program. Participating cord blood banks are also required to be otherwise accredited.

Other Standards

WBMT: The Worldwide Network for Blood & Marrow Transplantation is a collaborative research and educational non-governmental body consisting of the world's foremost blood and marrow stem cell transplant organizations that exists to promote excellence in this field. Through its accreditation committee, WBMT has created a cross-walk comparing various voluntary standards; and begun development of minimal core standards in hematopoietic cell transplantation for application in developing countries.

WMDA: The World Marrow Donor Association is a global association whose mission is to foster the international availability of high-quality stem cell products and to promote the interests of stem cell donors. The WMDA has voluntary standards and an accreditation program for donor registries. WMDA Standards promote the quality of procedures necessary to obtain, in the shortest possible time, an appropriate quality and quantity of hematopoietic stem cells from the best unrelated donor, while also protecting the anonymity and well-being of the volunteer donors. Since 2003, 20 of the 71 stem cell donor registries have become accredited by WMDA, accounting for approximately 75% of hematopoietic stem cell donors and cord blood units listed in the database of Bone Marrow Donors Worldwide.

Future directions

In an era when regulation and voluntary professional standards coexist, and when changes in healthcare delivery will place increasing importance on defining and meeting validated quality metrics, the field of blood and marrow transplantation has pioneered an accreditation system that could be adapted by other specialties. It is important that the professional organizations continue to lead the field by setting those quality standards demonstrated to be important in patient outcome, to provide the educational materials necessary for programs to meet and exceed regulations, and to continue communication with regulatory bodies to ensure clear understandings and enable appropriate regulation. Biannual liaison meetings between representatives of the Center for Biologics Evaluation and Research, the Office of Cellular, Tissue and Gene Therapies, and the professional societies representing active professionals in the cellular therapy community continue as a venue for the communication by industry of issues of concern.

Regenerative medicine applications of numerous cellular therapy products are expanding rapidly. Both autologous and allogeneic products are in clinical trials; and arguments continue to be made that at least some of these products should not require regulation [52]. The next years will define which of these products will prove useful, which if any will be designated as practice of medicine, and which will be regulated as biologic products.

To address needs in these emerging and evolving areas that include cellular therapies, FACT has recently published FACT Common Standards for Cellular Therapies [53]. These Standards represent the basic fundamentals of cellular therapy that can be applied to any cell source or therapeutic application, and are intended to be used throughout product development and clinical trials. The aim is improve outcomes in patients suffering from a variety of diseases and conditions. Ideally, various discipline-specific or product-specific standards will be added in the future with the input, collaboration, and acceptance of those experts actively involved in the specific field and their clinical and laboratory programs who volunteer to contribute and comply with them.

CHAPTER 37

Bone Marrow and Peripheral Blood Cell Donors and Donor Registries

Dennis L. Confer[1], John P. Miller[2] and Jeffrey W. Chell[2]

[1] Department of Medicine, University of Minnesota; and National Marrow Donor Program, Minneapolis, MN, USA
[2] National Marrow Donor Program, Minneapolis, MN, USA

Introduction

Hematopoietic cell (HC) donors provide bone marrow or peripheral blood progenitor (hematopoietic) cells (PBPCs) for more than 20,000 allogeneic HC transplant (HCT) recipients annually. In the United States, annual HCT using unrelated donors exceed those using related donors, but not to the extent expected given that at least 70% of HCT candidates lack a suitably matched family donor. This suggests that a significant fraction of the potential patient population is currently not being served. As unrelated donor registries grow and international collaboration increases, more patients will have the opportunity for transplantation. Even under the most optimistic scenarios, however, alternative approaches will also be necessary. Umbilical cord blood transplantation (see Chapter 39) and haploidentical transplantation (see Chapter 45) are strategies that will play increasingly important roles in meeting the needs of patients.

This chapter discusses the evaluation of HC donors, the risks and side effects of donation, and the logistics of HC collections.

Products from HC donors

Bone marrow was once the only graft source for allogeneic HCT [1–4], but since 1995, the role of PBPC has been clarified and its use increased dramatically. Data from the Center for International Blood and Marrow Transplant Research (CIBMTR) show that in the period 2006–2010, 80% of adult allogeneic transplant recipients received PBPC grafts [5]. National Marrow Donor Program (NMDP) statistics confirm dramatic growth in the use of PBPCs for unrelated donor transplantation (Figure 37.1).

PBPCs are now the most common choice for both autologous and allogeneic transplantation worldwide. Under normal physiologic conditions, a small number of $CD34^+$ HCs circulate in the peripheral blood, but their concentration is too low to enable efficient collection of an adequate dose for transplantation. However, in the mid-1980s, it was demonstrated that HCs could be mobilized from the bone marrow into the blood following chemotherapy and/or administration of hematopoietic growth factors such as rhG-CSF (filgrastim, Neupogen®) and rhGM-CSF (sargramostim, Leukine®). Around the same time, advances in apheresis instrumentation and collection techniques occurred such that an adequate number of mobilized HCs ($1.0–5.0 \times 10^6$ CD 34^+ cells/kg of patient weight) could be collected from the patient (in the case of autologous transplantation) or an allogeneic donor in one to three daily large-volume apheresis procedures.

Donors of allogeneic bone marrow and PBPC

Donors of bone marrow and PBPCs for allogeneic transplantation are either blood relatives of the transplant recipients or unrelated, anonymous volunteers. Related allogeneic HC donors are usually first-degree relatives of their recipients. Most are full siblings because of the much higher likelihood of complete HLA identity. The family of genes responsible for encoding the proteins of HLA A, B, C, and DR are co-located in a short region on chromosome 6, and as such are usually inherited *en bloc* as a single haplotype. Thus, there are only four combinations possible with the two haplotypes of each parent. Between two siblings, the likelihood of two identical HLA haplotypes, a single identical haplotype, and no identical haplotypes is, therefore, 25%, 50%, and 25%, respectively. A parent and their offspring are usually only half-matched (haploidentical) except in the uncommon situation where both parents happen to each possess an identical or nearly identical haplotype. Given that the average size of a modern family is just over two offspring, when one child needs an allogeneic transplant, the likelihood of an HLA-identical sibling match is 25–30%. The likelihood of a haploidentical match (full-sibling, half-sib, parent or child) is much higher, and successful strategies using such donors continue to evolve (see Chapter 45).

Unrelated donors and unrelated donor registries

Most potential transplant candidates do not have a fully HLA-matched family donor, a limitation that became apparent early in the history of allogeneic transplantation. By the early 1970s, however, case reports began to appear documenting the feasibility of HCT from HLA-matched unrelated donors [6]. Such donors were usually gleaned from the files of HLA-typed platelet donors at community blood centers or large hospitals. In 1974 in the UK, the Anthony Nolan Registry was established and dedicated to recruiting and maintaining a file of HLA-typed volunteer bone marrow donors. Within a few years, similar efforts were established in countries throughout Europe, the Americas, and Asia.

Thomas' Hematopoietic Cell Transplantation, Fifth Edition. Edited by

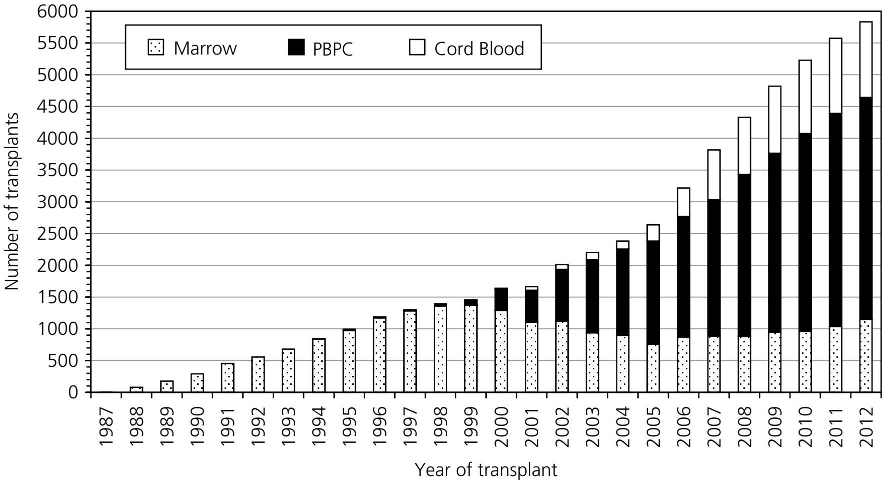

Figure 37.1 Annual transplants from unrelated donors facilitated by the National Marrow Donor Program since its inception. Annual figures include products collected outside the United States and imported, as well as those collected within the USA and exported. Prior to July 1999, only bone marrow was used for initial transplantation, but PBPC were available in the setting of re-transplantation. Stippled bars = bone marrow; solid bars = PBPC; and open bars = cord blood units.

Today, most of the world's unrelated donor registries collaborate under the auspices of the World Marrow Donor Association (WMDA). The WMDA was organized in 1988 to promote international cooperation and the exchange of HC products [7,8]. The association has established standards and provides guidance on the organization and operation of unrelated donor registries [9].

The WMDA annually surveys unrelated donor registries around the world [10]. Seventy-three registries responded to the 2012 survey. Together, these registries listed more than 22,300,000 potential unrelated HC donors. Approximately 89% of these donors have been tissue typed for HLA A, B, and DR, while the remainder has been typed only for HLA A and B. Most of the registries serve one or more transplant centers in their country; together the registries reported 1399 transplant centers with potential access to unrelated donors. The Japan Marrow Donor Program reported the largest number of transplant centers with 222.

The WMDA respondents reported collecting 15,114 unrelated donor marrow and PBPC products in 2012. In 6927 instances (46%) the collected products were exported to another nation. Germany performed 6265 collections in 2012, which was the most of any nation and represented 41% of the world total. Germany exported 4384 (70%) of the products collected, mostly within the EU and to North America. The United States was the largest consumer of HC products with 3763 (25% of the world total) of which 1485 (39%) were imported. Worldwide, PBPC and bone marrow collections numbered 10,988 (73%) and 4126 (27%), respectively.

Much of the world's available inventory of unrelated adult donors and cord blood units can be accessed through Bone Marrow Donors Worldwide (BMDW). HLA data from 67 registries and 46 cord blood banks representing more than 20.7 million adult donors and 560,000 cord blood units were listed by BMDW at the end of 2012. BMDW provides a highly important resource, but is limited by incomplete participation and lack of comprehensive search and fulfillment functionality.

The largest registry in the world is the NMDP with more than 6.7 million United States registrants followed by the German National Bone Marrow Donor Registry (ZKRD) with more than 4.8 million. The NMDP adds about 500,000 new donors annually. The vast majority of these are recruited at community donor drives, which are held at numerous locations including blood centers, college campuses, community centers, sporting events, and homes of worship. More than 1000 drives are held each month. New recruits are screened to confirm good health and the absence of serious transmittable diseases, for example HIV.

Once a donor is recruited to a registry, it may be months or years before that donor's identification code appears on a patient search. At that time the donor may or may not be available for further testing and evaluation. Reasons for this include obsolete contact information, changes in the donor's health, or changing donor priorities. In the WMDA survey of registries, among 113,422 total donor requests for blood samples, 44,489 (39%) were canceled for donor reasons [10]. Donor availability in the United States is somewhat worse than the world average; in 2012, 44% of nearly 36,000 requests for donor blood samples were cancelled for donor reasons.

Donor eligibility and qualification

Prior to HC donation, donors must be evaluated to ensure that: (1) they can safely donate, (2) their HC will be safe for the recipient, and (3) they understand fully what they are being asked to do [11].

Regulatory requirements

In 1997, the US Food and Drug Administration (FDA) proposed an approach to regulation of human cells and tissues designed to minimize the risk of contamination and maintain the integrity and function of cell- and tissue-therapy products, including PBPC and umbilical cord blood HC (bone marrow for transplantation remains exempt from these regulations because of Congressional legislation) [12]. Subsequently, in 2004, the Food and Drug Administration published three final rules in the US Code of Federal Regulations that describe, among other things, the requirements for registration of establishments that "manufacture" HC, for determination of donor eligibility, and for compliance with Good Tissue Practices [13]. The FDA determined that minimally manipulated PBPCs and umbilical cord blood HC, collected from *related donors*, would be regulated under Section 361 of the Public Health Service Act. These regulations are intended to reduce the risk of transmission of relevant communicable diseases, either acquired from the donor or introduced into the products during manufacturing. For HC products from *unrelated donors*, however, the FDA felt there was a need for additional manufacturing controls, and chose, therefore, to regulate these products under Section 351 of the Public Health Service Act. Section 351 sets additional requirements for Good Manufacturing Practices, which must be followed to ensure the safety, potency, and efficacy of HC products from unrelated donors. Where Section 351 is silent, for example donor eligibility, Section 361 requirements apply. The FDA regulatory framework is not unique; similar regulatory frameworks have arisen in the European Union, Canada, Australia, and elsewhere.

A uniform feature of every regulatory system is establishment of controls to prevent transmission of infectious agents by HC products. There are numerous infectious diseases that if present in the HC donor would pose definite or theoretical risk to the transplant recipient. It is clear that HC can transmit many of the same infections that are transmissible by blood transfusion including hepatitis B (HBV), hepatitis C (HCV), and human immunodeficiency virus (HIV). In addition, some congenital or acquired conditions in the donor, such as genetic defects and immune system abnormalities, may be transmissible to the recipient. Minimizing the risk of disease transmission requires combining the information obtained from a targeted behavioral/medical history, a search for the physical signs of disease, and the results of laboratory testing for specific pathogens [14,15].

HC donors, similar to blood donors, complete a written questionnaire that has been specifically designed to elicit medical history and identify behaviors or activities that may increase the risk of infectious disease transmission [14,15]. Questions regarding high-risk behaviors, non-prescription drug use and skin-breaching procedures, such as tattooing and piercing, are included, as well as questions to assess residence in regions where exposure to malaria or the agent of bovine spongiform encephalopathy may occur. The donor screening questionnaire is intended to detect information that may place the transplant recipient at increased risk for transplantation-transmissible diseases. Testing of the donor's blood cannot substitute for direct questioning because the donor might have a "window-period" infection, the blood tests may be falsely negative or, equally important, the testing does not include all potentially transmissible diseases. Indeed, suitable screening blood tests for some disorders, such as Creutzfeldt–Jakob disease and variant Creutzfeldt–Jakob disease, do not currently exist. Positive responses on a proper donor-screening questionnaire may lead to donor disqualification or the donor may be determined to be ineligible by FDA criteria. Donors may also become ineligible as a result of physical examination findings or testing for relevant transmissible infectious diseases as described later.

In the United States, FDA regulations provide a mechanism for collecting HC products from ineligible donors [14,15]. In this case, the transplant physician may determine that there exists a state of "urgent medical need," which means that a suitable alternative donor or graft source is not readily available and the risks of alternative therapies are greater than the risk of proceeding with the ineligible donor. If the transplant physician elects to proceed with an ineligible donor, the declaration of urgent medical need must be documented and appropriate paperwork and labeling must accompany the PBPC product. It should be emphasized that donor eligibility from a regulatory standpoint is distinct from donor suitability. A donor may be eligible, but have medical conditions, as described later, that make him or her unsuitable for donation.

The donor physical examination, discussed in greater detail later, should detect behavioral and experiential stigmata, such as recent tattoos, piercings, illicit drug use, and so on, as well as signs of significant conditions, including specifically sepsis and vaccinia [14]. In addition, a sample of the donor's blood must be tested within 30 days prior to donation for at least the following infectious diseases: HIV 1/2, HBV, HCV, *Treponema pallidum*, human T-cell lymphotrophic virus I and II, West Nile virus, and cytomegalovirus (CMV). For infusion in the United States, testing must be performed in a certified laboratory, which uses test kits specifically licensed or approved for donor screening and which follows the test kit manufacturer's instructions. Testing that is performed with an unlicensed test kit or a test kit that is licensed for a different purpose (e.g., diagnosis or monitoring) is a violation of FDA regulations.

Testing of HC donors for Chagas' disease is not currently required, although FDA-licensed kits are available for this purpose. Testing for prior infections with varicella-zoster virus, Epstein–Barr virus, and toxoplasmosis, while not required, may also be desirable. The results of regulated and non-regulated infectious disease testing must be available and reviewed prior to the initiation of preparative conditioning therapy for the recipient [14–16]. Donors with a confirmed positive test for HIV must not donate. As already described, donors with prior exposure to HBV and HCV may be used when there are no suitable alternatives and the potential gain outweighs the risk. Issues related to hepatitis are fully discussed in Chapter 95.

Medical suitability

HC donation is not without risk. As described later, adverse events are uniformly encountered, but these are generally minor and short-lived. Serious adverse events, including death, may, however, occur. It is essential that prior to donation each donor is assessed to ensure the absence of conditions that might increase donor risk to unacceptable levels. To ensure objectivity and preservation of the donor's best interests, this assessment should be performed by a physician who is not directly involved in the care of the proposed recipient. O'Donnell et al. conducted a survey of transplant programs in the United States to assess current donor care practices [17]. This survey demonstrated frequent overlap in provider care transplant recipients and their related donors.

History and physical

The donor receives a medical history and physical examination appropriate for the anticipated donation procedure. The history, which addresses risk to the donor, as opposed to the screening history described earlier, should focus on matters relevant for the anticipated donation, including the psychologic issues discussed later. For all donors, these would include a review of known health problems, a listing of medication and allergies, and review of the family history. Marrow donors should be questioned about prior surgical procedures and types of anesthesia received. Marrow donors should also have a careful review of systems directed toward neurologic, respiratory, cardiovascular, and musculoskeletal problems. PBPC donors should be questioned about prior whole blood or apheresis donations. The review of systems for PBPC donors should include a careful cardiovascular and neurologic review as well as specific questions about a history of venous access problems, autoimmune diseases, and splenic disorders.

The donor's physical examination should focus upon the neurologic, respiratory, and cardiovascular systems. In addition, marrow donors need an assessment of the oral airways and an evaluation of access to the iliac crests. Donors with a history of musculoskeletal symptoms need a careful examination of the spine and lower extremities. The examination of PBPC donors should additionally include evaluation of venous access and an abdominal examination for splenomegaly.

Laboratory and procedural evaluations of donors

The laboratory evaluation of all HC donors typically includes the following: complete blood count with white blood cell differential, ABO/rhesus grouping, serum electrolytes, glucose, alanine aminotransferase (ALT), bilirubin, creatinine or blood urea nitrogen (BUN), total serum protein and albumin, and prothrombin time and partial thromboplastin time [11]. Some physicians will also recommend evaluations of immunoglobulin levels and a screen for monoclonal proteins in the blood. Additional evaluations of donors may include urinalysis, chest X-ray, and electrocardiogram.

HC donors whose intended recipients suffer from inherited conditions, such as hemoglobinopathies or inborn errors of metabolism, may require specific testing to rule out carrier states that could affect transplant outcome. Donors with sickle cell trait and thalassemia minor can serve as donors in successful bone marrow transplants. As discussed later, however, donors with S-beta thalassemia, SC or other complex sickle hemoglobinopathies should not receive rhG-CSF.

A pregnancy assessment must be performed for female donors with childbearing potential [11]. Pregnancy is considered a contraindication to marrow donation; however, successful marrow collection from pregnant donors has been reported [18]. Pregnant women cannot be PBPC donors as hematopoietic growth factor administration is contraindicated.

Ethical and psychosocial issues

Psychologic aspects of marrow donation

The psychologic condition of the donor should be assessed. In particular, what are the donor's motivations for considering the HC donation? Is the donor acting out of a genuine desire to help, or are there other motives involved – perhaps an unrealistic expectation of reward or personal gain?

Switzer et al. [19] interviewed 343 unrelated marrow donors prior to donation, then immediately, and 1 year post-donation. They determined that donor motives could be classified into six categories and that an individual donor might express motives in more than one category. Donor motives varied between men and women and were associated with reported levels of pre-donation ambivalence and with both psychologic and physical difficulties post-donation [19].

Compared to unrelated donors, related donors may have different motivations and may be subject to increased emotional and physical stress [20]. Discussions of the psychologic issues affecting donors post-donation are presented in Chapter 32.

Occasionally donors may be subjected to coercion. Switzer et al. [19] have reported that unrelated donors who feel they were pressured, either encouraged or discouraged about donation, are less likely to have a positive donation experience.

Donor consent for HC donation

HC donors must provide written consent prior to donation [11]. The model of informed consent for research is appropriate for the HC donor even in the absence of planned research.

HC donors as research subjects

It is important to determine circumstances that make the HC donor a bona fide research subject. This can be complicated because much of the research involving HC donors also involves the HCT recipient. Several tests may be applied to help determine whether a particular activity constitutes research involving the HC donor. These include the following: (1) Is there collection of individually identifiable information or product for the purpose of research?; (2) Is there collection of information or product in support of an FDA IND application or an FDA Investigational Device Exemption (IDE)?; and (3) Is there an interaction with a donor that would not be occurring in the absence of the research? Affirmative responses to any of these questions serve to define research [21].

Remuneration of donors

Donor registries reimburse the unrelated donor for any out-of-pocket expenses related to their donation. Remuneration, however, that is, direct payment of cash or other valuable consideration, has been thoughtfully avoided. The mission of the registries is service to patients in need of blood or marrow transplantation, and the entire pipeline works to meet that need beginning with the humane, altruistic volunteer donor. Some have speculated that more people would donate if they were offered cash payment or other valuable consideration. However, such remuneration of the donor disrupts the pipeline, suddenly creating two persons in need, the recipient who is still in need of HCT and the donor who needs to be paid for inducement; for the latter, the mere prospect of saving someone's life is not sufficient motivation.

Standards of the WMDA and Guiding Principles of the World Health Organization both prohibit direct payment to volunteer donors [22,23]. The practice of the world's donor registries in service to their patients has been strict adherence to these principles. In the US, this practice was recently challenged by a legal decision from the 9th Circuit Court of Appeals [24]. The Court held that although the National Organ Transplantation Act [25] prohibits direct payment to donors of bone marrow and "subparts thereof," the Act does not prohibit payment to PBPC donors. The Court held that PBPCs do not represent a subpart of the bone marrow, but rather a subpart of blood. The exact mechanism by which PBPCs reconstitute the entire hematopoietic system without being a subpart of the bone marrow was not addressed in the Court's opinion. Thus far, donor registries in the United States, including the NMDP, have continued their policies of non-remuneration for donors. The issues of remuneration for HSC donors have been carefully described by Boo et al. [26].

Donation procedures

Bone marrow

Marrow is typically collected from the posterior iliac crests of the donor under general or regional anesthesia. The posterior superior iliac spine is the primary landmark for initiating the marrow collection. Marrow is aspirated through large bore needles into glass or plastic syringes that have been rinsed with a heparin-containing solution.

Typically, the iliac crest is entered through a skin puncture or a small skin incision. Once the cortical bone has been penetrated, a small amount of marrow (5–10 mL) is aspirated by applying vigorous suction. The syringe is removed and its contents are immediately transferred to an anticoagulant solution. Commonly, the aspiration needle is then advanced several millimeters and the process repeated. Several aspirations may be obtained from a single bone puncture as the needle is repeatedly advanced. Through a single skin entry site, the bone may be entered multiple times. A typical collection may involve 200–300 marrow aspirations obtained through a few or several skin punctures or incisions. Occasionally, marrow is also collected from the anterior iliac crests.

The aspiration of marrow produces an admixture of marrow cells from the bone cavity and capillary blood. The ratio of marrow to blood appears to depend upon the technique employed. Short, vigorous aspirations are generally thought to produce a higher concentration of marrow cells relative to peripheral blood. Even though the dilution of marrow cells with peripheral blood is variable, the adequacy of marrow collections is determined by the nucleated cell count of the mixture. For many years, the target cell dose for allogeneic marrow collection was $>2.0 \times 10^8$ nucleated cells/kg recipient body weight. Sierra et al. [27] evaluated the effect of marrow cell dose in 174 unrelated donor bone marrow transplant patients with high-risk acute leukemia. Their analysis showed a beneficial effect of marrow cell doses above the study group median (3.65×10^8 nucleated cells/kg). As a result of this analysis and similar studies, many centers now routinely seek marrow cell doses of 4×10^8 nucleated cells/kg.

Peripheral blood HCs

The PBPC collection site is usually a blood center or the apheresis unit of a hospital. Donors typically remain as outpatients throughout the mobilization and collection process. Filgrastim is currently the most commonly used mobilizing agent although lenograstim (not available in the USA) yields similar numbers of $CD34^+$ cells [28]. Although also not yet licensed in the USA for normal donors, the CXCR4 antagonist AMD 3100 effectively mobilizes PBPCs in autologous and allogeneic donors [29]. The rate of engraftment with cells from related donors appears similar for the filgrastim- and AMD 3100-mobilized PBPCs [29].

Filgrastim is usually administered at a daily dose of 10–16 μg/kg donor weight, which may be given as a single subcutaneous injection or divided into twice-daily injections. PBPCs are collected using a continuous-flow cell separation device. Collections begin after the fourth or fifth dose of filgrastim.

There is wide variability between donors in the number of $CD34^+$ cells that will be mobilized and collected following stimulation with filgrastim. The exact dose of $CD34^+$ cells appropriate for allogeneic transplantation has also not been established, but the usual target is $4–6 \times 10^6$ $CD34^+$ cells/kg recipient weight [30,31]. For the majority of adult recipients, it appears that one or two 12 L aphereses, or a single large volume procedure, will provide sufficient HCs for successful engraftment.

Adverse events associated with hematopoietic cell donation

An adverse event is any untoward medical occurrence. Serious adverse events are those adverse events that pose a threat to the individual's life or functioning. Serious adverse events include at a minimum adverse events that are: (1) fatal, (2) immediately life threatening, (3) require or prolong hospitalization, (4) result in a significant or persistent disability, or (5) represent a congenital anomaly. Both marrow and PBPC donations are associated with adverse events. Fortunately, serious adverse events are not common. In the NMDP experience, hospitalization is the most common reason for an adverse event to be rated as serious. Unexpected adverse events, which may be either serious or not, are those that are not described in a protocol, consent form, Investigator's brochure, or the medical literature.

Pulsipher et al. recently reported on the NMDP's collection of adverse events from nearly 10,000 bone marrow and PBPC donors [32]. Data were prospectively collected on 2726 bone marrow and 6768 PBPC donors between 2004 and 2009. Time points for data collection were at baseline, during donation procedure, and following donation. After donation, donors were contacted within 2 days and then weekly until reporting full recovery; all donors were also contacted at 1 month, 6 months, and annually after donation. All collections were performed at NMDP-approved sites. PBPC were collected according to an NMDP-sponsored research protocol, which operated under an Investigational New Drug application filed with the US Food and Drug Administration. Characteristics of bone marrow and PCSC donors were similar and overall 61% of donors were male. Eighty-six percent of bone marrow donors received general anesthesia with the rest having epidural or spinal anesthesia. Seventy-seven percent of PBPC donors donated with a single apheresis procedure. Anemia was more common after bone marrow donation, but only 0.5% of bone marrow donors received homologous blood transfusions. Thrombocytopenia was more likely following PBPC donation with platelet counts <150,000/mcL occurring in more than 50% of donors and counts <100,000/mcL in 26%. All blood counts returned to near baseline levels within 1 month and remained so in annual follow-up out to 3 years.

Bone pain occurred in more than 80% of donors irrespective of donation type. The character of bone pain was similar in the two groups with the vast majority experiencing mild to moderate discomfort. The timing of bone pain was obviously different with PBPC donors experiencing most pain during filgrastim administration and prior to donation, while bone marrow donors experienced pain after the donation. Bone marrow donors were more likely to report persisting pain at both 1 week and 1 month post-donation. Other side effects, such as fatigue, insomnia, and constitutional symptoms were similar in the two groups irrespective of the donation type. Women were more likely to experience pain and other symptoms than were men. Older donors were more likely to report pain and other symptoms 1 week post-donation.

In the Pulsipher report, 21% of women required central venous catheter placement for PBPC collection as opposed to just 4% of men [32]. Women were also more likely than men to require unplanned hospitalization in association with either type of donation.

Consistent with the Pulsipher study, Rowley et al. [33] reported the experiences of 69 sibling donors who participated in a randomized comparison of bone marrow and PBPC transplantation. The frequency and intensity of symptoms between the two groups of donors was no different.

Additional adverse events specifically associated with marrow donation

Minor complications occur in 6–20% of marrow donations [32,34,35]. These include such events as hypotension, syncope, severe post-spinal headache, excess pain, and minor infections. By definition, these complications resolve within a few to several days of onset.

Laboratory and radiologic abnormalities also accompany marrow donation. Anemia is the most significant laboratory finding. Marrow harvesting also causes significant, but transient, elevations in serum alkaline phosphatase and ostoecalcin [36]. X-rays, CT scans and radionuclide scans disclose abnormalities in the pelvis and sacrum that may persist for weeks or months [37].

Serious adverse events following marrow donation

The frequency of serious adverse events following marrow donation is estimated at 0.1–0.3% [38]. A review of data collected between 1969 and 1983 on 2248 allogeneic marrow donations reported to the International Bone Marrow Transplant Registry (IBMTR) and 1160 additional donations occurring in Seattle revealed nine total incidents (0.27%) [39]. These included one case of aspiration pneumonia, two cases of deep vein thrombosis (including one occurrence of pulmonary embolism), three serious bacterial infections (including two with bacteremia), two instances of serious cardiac arrhythmia, and one case of cerebral infarction.

The medical literature also contains reports of serious infections following marrow collection [34,39]. Infectious osteomyelitis appears to be a relatively rare complication following marrow collection [40,41].

Hemorrhage associated with the collection can create severe pain from compression of soft tissues. Sciatic pain lasting up to 18 months has been reported in a related marrow donor [34]. Prolonged and significant pain may occur following marrow collection, leading to permanent disabilities. Fractures of the iliac crests have also been reported [34].

Marrow donation and the risk of death

Death has occurred among normal marrow donors. A review of 7857 marrow collections reported to the CIBMTR revealed two deaths [42]. Table 37.1 lists 11 documented deaths occurring within a few days of HC donation [43–46]. As is evident in Table 37.1, two deaths actually occurred prior to scheduled marrow donations. Whether the stress of impending donation somehow contributed to these events is unknown. Similarly, it is difficult to know whether death in the days immediately following HC donation is causally related.

Additional adverse events associated specifically with PBPC donation

Bone pain is the most prominent adverse event among PBPC donors occurring in 25–86% of donors receiving filgrastim [47,48]. Bone pain likely results from altered bone metabolism, which is reflected by increased bone-derived alkaline phosphatase and decreased serum osteocalcin. The pain is typically diffuse but most prominent in the spine, hips or pelvis, and ribs [48]. Headache is also common. The discomfort from bone pain improves with mild analgesic therapy, such as acetaminophen or a non-steroidal anti-inflammatory drug (NSAID). Other symptoms seen with filgrastim include nausea and vomiting (~10%), myalgia (~20%), fatigue (~15%), insomnia (~10%), and injection site reactions (rare). Symptoms are probably less frequent at filgrastim doses below 10 μg/kg daily. Pain symptoms resolve promptly with discontinuation of filgrastim, and are rarely sufficient to cause premature cessation, or even dose reduction [32,48].

HC mobilization with filgrastim also causes numerous alterations in serum chemistries and blood cell counts. Lactate dehydrogenase, AP and ALT increase two- to fourfold after five daily doses of filgrastim. The white blood cell (WBC) count and in particular the absolute neutrophil count (ANC) increase dramatically during filgrastim therapy [32,48]. These increases are dose-dependent. At daily filgrastim doses of 10 μg/kg or greater, the total white count may reach 70–80 × 10^9/L by day 5. Eighty to 90% of the white cells will be neutrophils or band forms. It is generally recommended that the filgrastim dose be reduced if the WBC exceeds 70–75 × 10^9/L.

The apheresis procedure used in PBPC collection is also a source of adverse events. Anticoagulation with acid-citrate-dextrose (ACD) solution may elicit symptoms of hypocalcemia – perioral numbness, paresthesias, and carpopedal spasms. These symptoms may be ameliorated with oral calcium supplementation, but are more effectively managed with an intravenous infusion of calcium during apheresis. Reducing the blood flow rate may also improve symptoms of hypocalcemia, but at the expense of prolonging the collection procedure. Another approach that has been used is to supplement the anticoagulation with heparin to diminish the amount of ACD required [49].

Thrombocytopenia is the most consistent and significant finding with PBPC apheresis [32,48]. The pre-apheresis platelet count reproducibly declines between 20 and 30% with each collection and does not begin to recover until 3–4 days after the last collection. Following two procedures, it is common to encounter total platelet counts below 100 × 10^9/L.

Table 37.1 Deaths occurring in association with hematopoietic cell donation

Age	Sex	HSC source	Proximity to donation	Cause of death	Ref.
40	M	marrow	prior	cardiac arrest	[81]
46	M	marrow	prior	cardiac arrest	*
57	F	marrow	immediate	v. fibrillation	*
35	M	marrow	immediate	respiratory arrest	*
35	F	marrow	immediate	myocardial infarction	*
35	M	marrow	after	pulmonary embolism	*
47	F	PBPC	immediate	sickle crisis	[83]
57	F	PBPC	after	stroke	[84]
62	F	PBPC	after	cardiac arrest	*
6	M	PBPC	after	cerebral hemorrhage	*
19	F	PBPC	before	hemopneumothorax	*

*Personal communication to the authors.

Serious adverse events following peripheral blood hematopoietic cell donation

Filgrastim administration may precipitate severe sickle crisis in persons with sickle cell anemia or complex sickle cell hemoglobinopathies [43,50]. Indeed, a 47-year-old woman with Hb SC disease, who had never had any symptoms from her condition, suffered a fatal sickle crisis during filgrastim mobilization of PBPC intended for her sister with CML [43]. It remains to be clarified whether persons with sickle trait (Hb AS) are at any increased risk from filgrastim. Kang et al. [51] safely mobilized and collected PBPC from nine donors with sickle trait. These donors did experience higher symptom scores during mobilization than did eight simultaneous control donors, but there were no symptoms suggestive of painful sickle crisis.

There have been several reports of spontaneous splenic rupture apparently related in some way to extramedullary hematopoiesis [52–55]. In three cases the spleen was surgically removed, but conservative management was effective in two cases. Platzbecker et al. [56] performed ultrasound evaluations of spleen size before and after rhG-CSF mobilization in 91 healthy PBPC donors. Although no adverse splenic events occurred in this group, significant increases in spleen length and width were routinely documented. No donor factors or clinical findings (change in WBC, increase in alkaline phosphatase, etc.) correlated with the degree of splenic enlargement. Similar findings were reported in independent studies by Stroncek et al. [57], which also demonstrated that splenic enlargement may persist for up to 10 days in some donors. Based on these studies, ultrasound does not appear to be useful for predicting the risk of hemorrhage into the spleen.

Growth factor is probably contraindicated in donors with a history of autoimmune disorders [58–60]. Flares of rheumatoid arthritis and ankylosing spondylitis have been reported in non-PBPC donors following therapy with filgrastim or sargramostim [58,60]. A variety of eye inflammatory responses have been reported among allogeneic PBPC donors. These have included marginal keratitis, episcleritis, and iritis occurring during therapy with filgrastim [59,61].

PBPC donation and the risk of death

As with bone marrow donation, death at the time of, or in close proximity to, PBPC donation has been reported [43,44]. Table 37.1 lists five deaths among PBPC donors. It is unclear whether the risk of death associated with PBPC donation differs from that of bone marrow donation.

Long-term donor follow-up

The long-term safety profile of growth factor therapy in normal individuals has not been established. Several investigators have performed serial evaluations on the peripheral blood of normal PBPC donors using a variety of techniques to evaluate chromosomal content, DNA stability, replication timing, and gene expression profiling [62–66]. In every instance, except one, filgrastim-induced alterations during HC mobilization have been transient; Nagler et al. [64] reported persistent aneuploidy of chromosome 17 in the lymphocytes of PBPC donors 6–9 months after mobilization. A recent study by Hirsch et al. could not replicate these findings and disclosed no evidence of filgrastim-induced aneuploidy or replication asynchrony [66].

There have been several reports providing 1–5 years follow-up on limited numbers of PBPC donors [30,48,67–70]. In no instance have serious adverse events attributable to filgrastim been identified. Pulsipher et al. reported on 2408 NMDP donors with a median follow-up of 49 months (range 0 to 99 months) [48]. Among these donors, no cases of acute leukemia were seen and a single case of chronic lymphocytic leukemia was reported. Anderlini et al. [71] recently reported on the follow-up of 343 PBPC donors of whom 281 (82%) were able to be interviewed. With a median follow-up of 39 months (range 7 to 80), there were no instances of leukemia or other hematopoietic adverse events.

PBPC versus marrow: which is easier for donors?

Switzer et al. [72] evaluated 70 unrelated bone marrow donors who subsequently provided a second HC product (25 PBPC and 45 bone marrow). Donors whose second product was PBPC reported that, in comparison to their prior bone marrow donation, PBPC donation was less difficult physically, required less time, and was more convenient. In the NMDP experience, PBPC donors recover from donation more quickly than bone marrow donors [32].

In randomized trials of PBPC versus bone marrow among sibling donors, the distinction between the two procedures is less clear. Similar levels of anxiety and pain are reported, and time to complete recovery may also be similar [73,74]. When differences are observed, however, in acute symptoms, fatigue, time to recovery or late complications, these tend to favor PBPC donation [74–76].

Special considerations

Infants and children as HC donors

Children may safely donate marrow [34,77,78]. They are probably more likely than are adults to receive allogeneic blood transfusion, but serious complications among children donors have been rare [34,78].

Sanders et al. [78] reported on 23 marrow donors under the age of two. Harvested volumes were between 11.5 and 19.3 mL/kg donor weight. No serious complications were encountered, but 22 of the 23 infants required allogeneic blood.

In a survey of pediatric marrow transplant physicians, only seven of 56 responders were unwilling to collect marrow from infant donors 0–6 months old [77]. There was little agreement, however, on the management of large volume collections. Of 52 respondents, six would limit collections to 25% or less of the donor's blood volume, whereas 24 placed the limit at 50% or higher. Twenty-two respondents preferred to manage large volume collections in two stages.

Children appear similar to adults with respect to their response to filgrastim and PBPC collection [79]. They tolerate filgrastim similarly and provide high yields of CD34$^+$ cells. Central venous access may be required more often for successful collection from children [79]. A report described PBPC collections in five children aged 4–13 years [49]. The children each received filgrastim at a dose of 6 μg/kg every 12 hours for 3 or 4 days. One or two leukapheresis procedures were performed. No child required a central venous line and no immediate complications were encountered. Pulsipher et al. [80] recently reviewed the clinical, ethical, and research issues surrounding administration of filgrastim to children.

Children who are being evaluated as potential HC donors deserve special attention. They may have very limited understanding of their family member's illness and of the donation process. Their fears and concerns are often complex and accompanied by significant ambivalence [81]. With hapoloidentical transplantation protocols, children may also be considered as donors for parents, which raises added concerns about understanding, stress, and informed consent.

Consent for children presents special concerns. In most instances, parents are expected to consent for their children, which may create conflict of interest situations. When they are later asked, children have reported that they were forced to donate by families or physicians or, short of being forced, that they felt they had no real choice in the matter [81].

A survey of pediatric transplant physicians in the United States confirmed that most felt the role of consent appropriately rested with the parents [77]. In some locales, it remains the standard practice to appoint legal guardians to determine whether HC donation is in the child's best interest.

Subsequent donations following an initial HC donation

A person can donate hematopoietic cells repeatedly. Most second donations of bone marrow or PBPC are intended for the original transplant recipient and used for treatment of graft failure, poor graft function, or disease recurrence. Buckner et al. [34] reporting on 1160 marrow donors identified 99 who donated marrow twice, usually within a 2-month period. There was a modest decline in the average total nucleated cells collected with the second donation. Stroncek et al. [82] reported on 16 second donation donors at the University of Minnesota. There was a trend toward lower total cells and lower cell concentrations in the second collections. When fewer than 90 days separated the collections, the decrement in cell concentration was statistically significant [82]. Donors whose second donation occurred within 60 days of the first were frequently transfused with allogeneic blood (5 of 8 within 60 days vs. 0 of 8 later than 60 days).

Consecutive PBPC collections are also feasible. Stroncek et al. [70] collected PBPC products 1 year apart in 19 healthy volunteers.

There were no differences in premobilization blood counts, the response to filgrastim stimulation, or the CD34$^+$ cell yield between the first and second collections. Similar results were reported by Anderlini et al. [30] who described 13 allogeneic PBPC donors providing a second donation at a median of 5 months (range 1 to 13). No differences were identified in preapheresis WBC counts of the donors or in the yield of CD34$^+$ HC. In more recent studies, de la Rubia et al. [83] noted a decline in the total CD34$^+$ cell yield following a second PBPC mobilization and collection. Donor symptoms were no different between the two donations. Similar results were noted by Platzbecker et al. [84] who also found that female sex and a low peripheral blood CD34$^+$ cell count during the first mobilization predicted for a low CD34$^+$ yield with the second donation.

The WMDA has published consensus guidelines for subsequent donations by unrelated donors [85]. These guidelines establish recommended intervals between donations and limits on the number of donations.

Growth factor-mobilized bone marrow

In efforts to accelerate the engraftment rate for bone marrow transplantation, investigators have explored filgrastim administration prior to bone marrow collection [86–88]. These reports, a combination of single arm trials and comparison studies, suggest indeed that rhG-CSF pretreatment of the marrow donor may accelerate recovery of neutrophils and platelets. Morton et al. [89] reported a randomized comparison between PBPC and filgrastim-primed bone marrow. Engraftment of neutrophils and platelets was not different between the two groups, but patients receiving filgrastim-primed bone marrow had significantly less steroid-refractory acute graft-versus-host disease (GVHD), less chronic GVHD, and fewer days of immunosuppressive therapy. Taken together, these preliminary observations suggest that it may be possible to gain some of the advantages of PBPC without the added risk for increased acute and chronic GVHD.

These studies, however, have important implications for HC donors because many of the most significant and non-overlapping adverse events of PBPC and marrow donation are combined in a single procedure. While reduced volumes of marrow collection may be possible [86], this may not fully offset the added risks of filgrastim administration. This would seem to be an area where carefully designed, prospective clinical trials are needed.

Summary

Allogeneic HC donation is safe. Serious adverse events are uncommon and death is exceedingly rare. Nevertheless, all donors must be carefully evaluated and fully informed prior to HC donation. Emerging regulatory requirements must be anticipated and met. The two common procedures for obtaining an HC graft, bone marrow and PBPC collection, differ in their acute and longer term impacts upon the donors. The safety data for both procedures is emerging and confirms long-term preservation of a functional, benign hematopoietic system.

It is highly likely that annual numbers of allogeneic HCTs will continue to grow. Based on estimates of current need, the numbers of related and unrelated allogeneic HCTs will easily double within the next several years.

CHAPTER 38

The Role of the Transplant Program in a Nuclear Accident or Terrorism

Nelson J. Chao[1] **and Dennis L. Confer**[2]

[1] Division of Hematological Malignancies and Cellular Therapy/BMT, Duke University, Durham, NC, USA
[2] Department of Medicine, University of Minnesota; and National Marrow Donor Program, Minneapolis, MN, USA

Introduction

The irony of this chapter should not be lost on the reader. After all, it was the nuclear detonations in Hiroshima and Nagasaki that led to the clinical observations that the bone marrow was very sensitive to the effects of radiation. Many of the victims of the nuclear detonations presented days later with pancytopenia. This bone marrow sensitivity led to the initial murine and then canine studies confirming that the bone marrow was the organ responsible for making all the blood elements and that bone marrow shielding or the transfer of bone marrow from another individual could rescue the animal from a lethal dose of radiation. Moreover, transplantation biology with the description of the major histocompatibility complex (MHC) was a direct result from these initial studies. This observation was then confirmed in humans with various maladies affecting the bone marrow or immune system who received total body irradiation followed by an autologous or allogeneic bone marrow graft. Thus the field of hematopoietic cell transplantation (HCT) was born. Our field has brought a combination of very exciting basic science, translational medicine, and clinical care to our patients leading to significantly better outcomes in many disease states. Yet, it seems we are coming around full circle with the increased threat of a nuclear detonation brought by a terrorist attack or a natural disaster.

Release of radioactivity, either intended or not, is an undeniable possibility and potentially catastrophic [1]. The recent tsunami and the Fukushima reactor meltdown is a stark reminder of the potential risk. If the winds had not been favorable blowing radioactivity out to sea, the effects could have been much worse [2]. Reports of nuclear proliferation in nations unfriendly to the United States and the Western world and the poisoning of a Russian dissident with polonium-210 are further reminders of the terrorist threat [3]. In addition, more than 400 radiologic accidents have occurred since 1944, resulting in over 3000 significant exposures [4]. Approximately 10 million "sealed sources" of radioactive material (e.g., cesium-137, cobalt-60) are used for medical, industrial, agricultural, and research purposes worldwide [5]. Over 600 of these have been lost or stolen since 1995 and less than half were eventually recovered.

Detonation of a nuclear device would cause unprecedented loss of life and injuries as well as economic, political, and social disruption. Many victims exposed to significant doses of radiation will develop bone marrow suppression. Thus, hematologists and oncologists, especially those with HCT experience, are uniquely suited to help evaluate and manage radiation exposure victims [6]. Depending on the scale of the event, there may be a national call for surge capacity. Hematologists, oncologists, and hematopoietic cell transplantation (HCT) specialists across the country could be asked to balance the needs of their local patient populations with requests to accept patient transfers or even travel to other institutions. Therefore, we must collectively prepare for this contingency. Since a nuclear detonation would be the most severe form of damage, the rest of the chapter deals with this contingency planning but the infrastructure suggested would be able to respond to a radiologic dispersal device (e.g., a "dirty bomb" or a radiologic source under a subway seat or in a park) or a nuclear power plant accident.

A public prepared to protect itself from fallout and an effective medical response could save tens of thousands of lives. Since 2001, all levels of government, academic institutions, and professional organizations have done significant work to enhance our ability to prepare for and respond to a nuclear detonation. In the public health and medical arena, notable achievements are several different publications and websites including The Planning Guidance for Response to a Nuclear Detonation [7], the multipaper series from the Nuclear Detonation Scarce Resources Working Group [8–23], health and medical educational material available from the Centers for Disease Control and Prevention (CDC) [24] and just-in-time material including algorithm-based management available on the Radiation Emergency Medical Management (REMM) website [25]. The Federal Emergency Management Agency (FEMA) along with interagency partners is developing improvised nuclear device (IND) national strategy and implementation plans.

Preparedness and planning for a nuclear detonation

Several types of events, either accidental or intentional, could result in radiation exposure (Table 38.1). Intentional events can be caused by radiologic exposure devices (REDs), radiologic dispersion devices (RDDs), and improvised nuclear devices (INDs). An RED is a radioactive source placed surreptitiously in a public space or other location. An RDD spreads radioactive material over a wide area, either using a conventional explosive (i.e., a so-called "dirty bomb") or via other means (e.g., by tainting the food or air supply). Although these devices would likely produce comparatively few fatalities, large numbers of people could be exposed to small doses, engendering widespread public confusion and anxiety. Victims of events involving RDDs or REDs would most likely be treated at centers near the incident, except in specific cases that require highly specialized care for

Table 38.1 The spectrum of potential events involving radioactive material. Numbers of deaths are rough estimates

Categories	Description	Number of deaths
Radioactive source accident	Loss or theft of a radiologic source (e.g., Goiana, Thailand)	0–10s
Nuclear reactor accident	Release of radioactive gas or material (e.g., Chernobyl)	0–100s
Radiologic dispersal device	Device or scheme for dispersing radioactive isotope (e.g., dirty bomb[a] or radioactive material in the food supply)	0–1000s
Radiologic exposure device	Radioactive material intended to expose people in the vicinity (e.g., cesium source placed on a train)	0–100s
Improvised nuclear device	Incorporates radioactive material intended to produce a nuclear explosion	1000s to >1,000,000

[a] Only a small fraction of deaths would be expected to result directly from radiation exposure.

burns or marrow suppression. It is unlikely that individual hematologists in other regions of the country would be involved.

In contrast, an improvised nuclear device (IND) using fissionable material such as plutonium or uranium would have devastating consequences and require the utilization of all available resources. A nuclear detonation produces both physical damage (trauma and burns) and radiation exposure. While the blast, heat and radiation zones overlap close to the epicenter, there can be major zones where there is physical injury without radiation (upwind glass breakage injuries) and others where there is radiation with limited or no physical damage to the infrastructure (fallout areas). The response to a nuclear detonation is organized around three physical damage zones (severe, moderate, and light); a dangerous fallout zone; and a variable fallout zone, designated (>10 mR/hr), in which response activities can occur but rescue time may be limited. The Radiation TRiage, TReatment, and TRansport (**RTR**) system overlays a functional response on these response zones (Figure 38.1) [26].

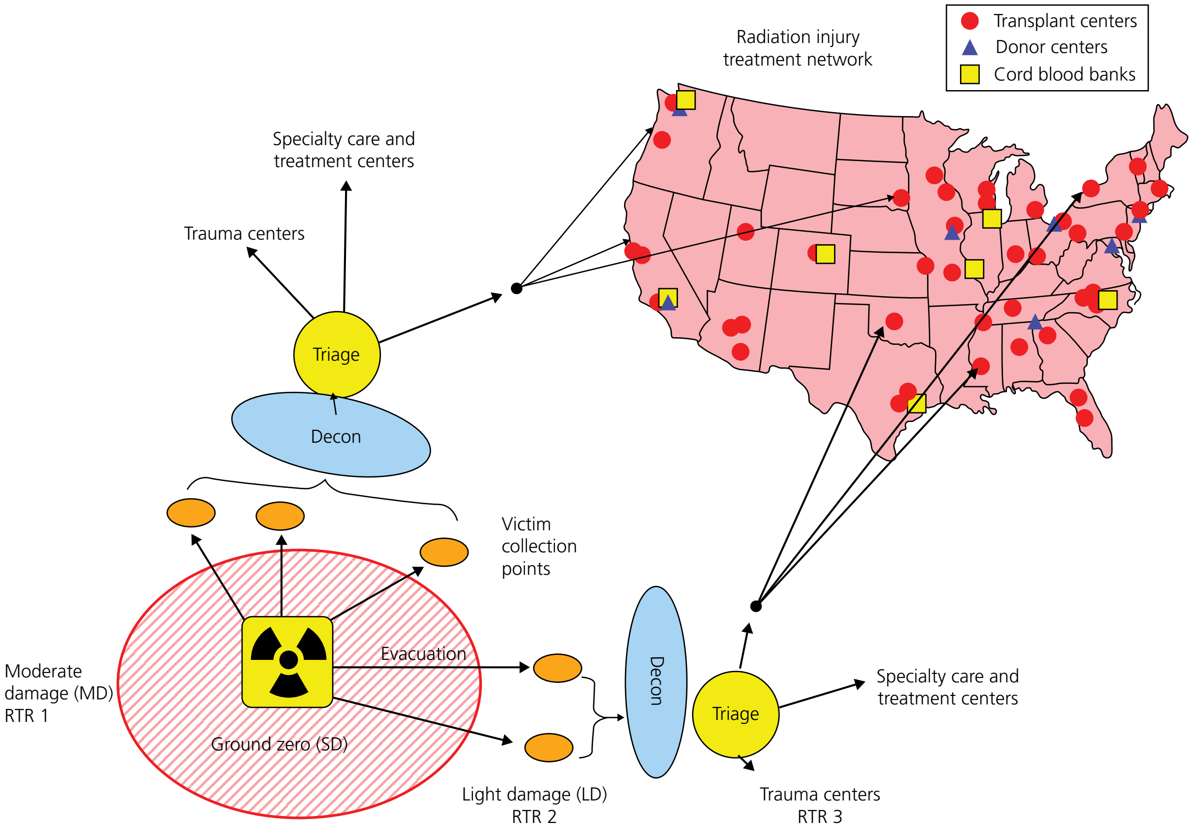

Figure 38.1 Schematic for triage and response to a large-scale radiation event developed by the Office of the Assistant Secretary for Preparedness and Response. Triage centers are located in concentric rings around the affected area, providing initial stabilization and decontamination (RTR 1–3), more extensive medical care (MC), and rapid screening of unexposed or minimally exposed individuals at assembly centers (AC). Patients who require further care are evacuated to referral centers in unaffected regions.

Damage Zones:

- Severe Damage (SD) zone: extensive infrastructure damage and few survivors
- Moderate Damage (MD) zone: probably not readily passable due to physical damage but can be cleared, with variable to no levels of radiation, which, if present, decrease fairly rapidly over time the first hours to day
- Light Damage (LD) zone: passable, most damage is glass breakage, with little or no radiation other than where fallout areas overlap the LD zone.

Functional Response System: the RTR system helps organize the response [6,7]. This system includes several types of sites:

Spontaneously forming RTR sites (casualty collection points):

1. RTR 1: at or near major physical damage with significant radiation present early on radiation present
2. RTR 2: limited physical damage and varying radiation present that declines over the first few hours to a day, likely near the dangerous fallout (DF) zone, and
3. RTR 3: minimal damage and no radiation.

It is estimated that approximately 40,000 hospital beds are available at any given time nationwide, a capacity far lower than the projected number of potentially salvageable casualties. Thus, medical centers around the country may be asked to accept patients from the disaster area, both victims of the event and local residents who require care for chronic or intercurrent medical conditions. These efforts would initially be coordinated as part of the National Disaster Medical System (NDMS), a federally coordinated system of public and private hospitals that augment the nation's medical response. As observed in the aftermath of Hurricane Katrina, healthcare needs for displaced populations can easily overwhelm the infrastructure in regions immediately surrounding a disaster area. For patients who require intensive medical care or those with cancer, hematologic disease or other chronic diseases, this disruption can be particularly dangerous.

Responding to the consequences of a nuclear incident: concepts, information and resources

Response is based on the assumption that resource availability will vary by proximity to the incident. Moreover, response will be an iterative process that will change over time. Hospitals closest to the detonation will be quickly overwhelmed by a surge of casualties and will rapidly exhaust supplies. The plan, therefore, is to distribute patients as quickly as possible for medical assistance farther away from the affected area where it will be easier to replenish supplies and staff. Key strategies for managing medical care in scarce resource settings are summarized in Table 38.2.

Developing a quantitative understanding of the local capacity for non-traditional emergency response assets (private practices, skilled nursing, commercial labs, etc.) and coordinating them is crucial. Planning for proactive resource support from the surrounding region, tribal, state, and Federal entities and the use of regional staging areas in case of a catastrophic incident will greatly shorten the time to resource availability to the end users. Assembly and evacuation center planning by healthcare facilities and the community at large will considerably mitigate bottlenecks and confusion in the hours and days after an incident.

Local planning is most effective when it is integrated across the tiers of response including state and Federal systems. Effective integrated planning is facilitated through the use of planning and response tools such as the Health and Human Services (HHS) resource mapping tool, MedMap [27]. MedMap facilitates sharing situational awareness with the local/regional responders and can show locations of healthcare facilities in relation to other overlays and demographic information. Designated local and state government partners can request access to MedMap through their HHS/ASPR Regional Emergency Coordinators.

Table 38.2 Strategies for scarce resource situations

- **Prepare** – stock disaster supplies and increase par levels on commonly needed items such as tetanus vaccines, laceration trays, narcotic analgesics, dressings, etc.;
- **Substitute** – use a clinically equivalent item or staff person [12];
- **Adapt** – use items or technologies to provide sufficient care (use transport ventilators or anesthesia machines instead of full-featured ventilators), use staff with similar or congruent skill-sets (specialty surgeons assisting with trauma surgeries), or adapt locations of care (performing surgical procedures outside of the OR environment);
- **Conserve** – use less of a resource by lowering dosage or changing utilization practices;
- **Re-use** – after appropriate disinfection/sterilization, re-use supplies;
- **Re-allocate** – prioritize a therapy in scarce supply so that it is only given to those with a higher chance of benefit or greater need.

Medical management of acute responses to radiation

People exposed to high levels of radiation (usually >1–2 Gy over a short period of time may develop acute radiation syndrome (ARS). Symptoms vary according to the dose but include vomiting, diarrhea, headache, dizziness, weakness, bleeding, and redness of the skin. In a large mass casualty setting, efficient triage of irradiated casualties is essential to identify those who have received clinically significant but not invariably lethal doses of radiation estimated at 2–10 Gy of whole body exposure. These are the victims that need specialized and sometimes urgent care. In resource-scarce settings, symptomatic care is given if possible and life-sustaining measures should be withheld from casualties with non-survivable trauma, thermal burns, and/or radiation exposures. Extensive triage algorithms that emphasize fairness were recently published to guide the selection of appropriate candidates for life-sustaining care in resource-limited settings in order to maximize survivability for the overall population [28] (See Table 38.3 for a list of websites containing additional information on approaches to medical triage, assessment and management after radiation exposure).

The current management of ARS does not substantially differ from the management of pancytopenia in other settings, such as after treatment with myelosuppressive chemotherapy. Although there are no cytokines currently licensed for treatment of acute radiation exposure, administering myeloid cytokines to appropriately selected victims offers two potential benefits after a mass casualty radiation incident. It can reduce morbidity and mortality resulting from neutropenia and it can lessen the need for subsequent or continued hospitalization during the post-incident period when medical resources and personnel may be extremely limited. The current challenge is that the local supply of cytokines would be quickly depleted in the absence of adequate triage to ensure that those that may not require this treatment immediately are referred for later evaluation and possibly treatment in a more resource-rich environment.

All patients with confirmed neutropenia or medical history of radiation exposure and physical injuries strongly suggestive of combined injury (radiation *plus* trauma and/or burns) are potential candidates for myeloid cytokines if they are deemed to have survivable exposure/injuries. Studies in non-human primates suggest that *initiating myeloid cytokines within 24 hours of exposure* may improve outcomes [29]. Myeloid cytokines [granulocyte colony-stimulating factor (G-CSF; filgrastim), granulocyte–monocyte colony-stimulating factor (GM-CSF; sargramostim) or pegylated G-CSF (pegfilgrastim)] can reduce the duration of neutropenia, hospital length-of-stay, and overall costs.

Myeloid cytokines should be initiated as soon as there is evidence a casualty will develop severe neutropenia (i.e., less than 500 neutrophils per mm^3). Specific indications for initiating myeloid cytokines prior to the onset of neutropenia include a projected whole body dose of 2 Gy or more based on (1) physical dose reconstruction using geographic information, (2) clinical signs, and/or (3) lymphocyte depletion kinetics. Drugs should be continued until normalization of the granulocyte count. Supportive care measures are equally important. Anti-emetics for vomiting, hydration, and antibiotics to prevent bacterial infections during the neutropenic period have been shown to improve survival in animal models of ARS. These suggestions are not different from those that are in daily practice in the hematology-oncology or transplant wards.

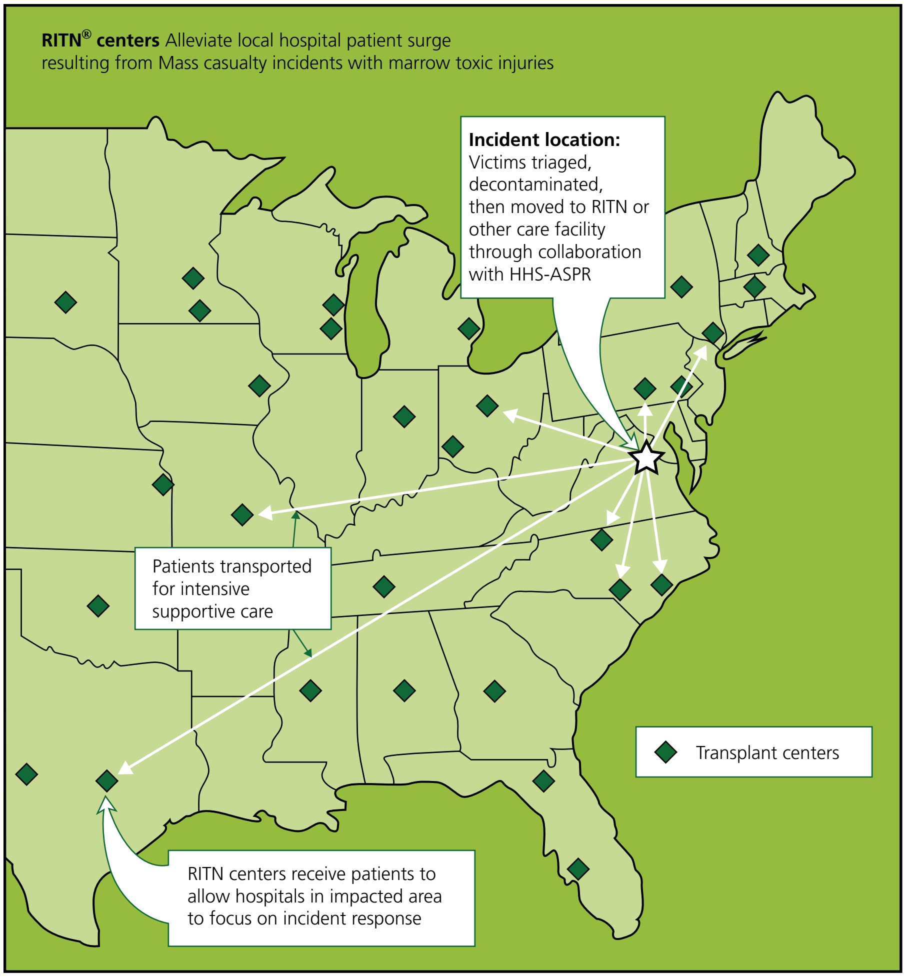
The essential role of biodosimetry

Appropriate triage and care after radiation exposure depends on accurate and timely estimates of radiation dose. Dose information will be important for classifying victims into groups that: (1) will not require medical intervention, (2) could benefit from supportive care (e.g., colony-stimulating factors) to facilitate autologous marrow recovery, (3) require evaluation for HSCT to treat potentially irreversible marrow damage, and (4) cannot be salvaged. A variety of information can be used to estimate an individual's radiation exposure. Unlike the homogenous dosing associated with therapeutic total body irradiation, shielding from nearby structures (e.g., buildings) during accidents or terrorist attacks will result in heterogeneous exposures. Therefore, a careful history of the victim's location and subsequent symptoms will be essential. Initial clinical assessment will include the time from event to first emesis and peripheral blood counts, with subsequent lymphocyte depletion kinetics.

Approaches that use only clinical and routine laboratory findings to stratify victims into risk groups are valuable for a small-sized accident, but their utility during large events is not clear [30–32]. Biodosimetry, the use of biologic markers to assess dose, can enhance the predictive value of clinical findings after radiologic or nuclear events. The "gold standard" for biodosimetry is the quantification of dicentric chromosomes using metaphase cytogenetics in peripheral blood lymphocytes (PBLs). Unfortunately, dicentric quantification requires multiple days to perform and is currently available only in select centers. Plans have been formulated to develop major radiation laboratory networks to perform dicentric quantification on a mass scale [33]. Newer methods for biologic dosimetry, including rapid genomic analysis of PBLs, serum proteomics, and measurements of DNA damage, are also under development [34–43]. Treating hematologists will need to calculate radiation doses using the information they have available. Online algorithms for estimating dose based on clinical and biologic data are available from the Radiation Event Medical Management (REMM) website at http://www.remm.nlm.gov/ars_wbd.htm or from the Armed Forces Radiobiologic Research Institute at http://www.afrri.usuhs.mil/www/outreach/biodostools.htm.

Radiation Injury Treatment Network (RITN)

Beginning in 2001, the National Marrow Donor Program (NMDP) established a working group to address the issue of a nuclear disaster. In 2006, the American Society for Blood and Marrow Transplantation (ASBMT) formally joined this effort and established the Radiation Injury Treatment Network (RITN), a voluntary consortium of 61 (and growing) HCT centers, donor centers, and umbilical cord blood banks (Figure 38.2), made possible through partnerships with the Office of Naval Research and the Center for International Blood and Marrow Transplant Research. The goals of RITN (www.ritn.net) are:



RITN® centers Alleviate local hospital patient surge resulting from Mass casualty incidents with marrow toxic injuries
Incident location: Victims triaged, decontaminated, then moved to RITN or other care facility through collaboration with HHS-ASPR
Patients transported for intensive supportive care
RITN centers receive patients to allow hospitals in impacted area to focus on incident response
Transplant centers

Figure 38.2 The Radiation Injury Treatment Network (RITN). Transplant centers, donor centers, and umbilical cord blood banks are divided into 10 regions designated by the US Federal Emergency Management Agency (FEMA). Primary transplant centers act as the lead institutions within their region during event response.

1. to develop treatment guidelines for managing hematologic toxicity among victims of radiation exposure,
2. to educate healthcare professionals about pertinent aspects of radiation exposure management,
3. to coordinate situation response after a radiation event,
4. to provide comprehensive evaluation and treatment for victims at participating HCT centers, and
5. to collect data on the outcomes of treatment.

The European Group for Blood and Marrow Transplantation (EBMT) is establishing a similar network to offer training courses and improve cooperation between institutions [29].

The number of patients who will require care after a large-scale event, such as an improvised nuclear device, exceeds the capacity of RITN centers by many orders of magnitude. For example, if a device similar to the bomb detonated over Hiroshima struck a metropolitan area, the number of casualties would depend on many factors, such as the size of the device, the time of day, type of buildings, weather conditions, and the precise location of the detonation. Models suggest that as many as 175,000 victims would require intensive medical care and nearly 30,000 would need intensive management for myelosuppression [44]. Such an event would clearly overwhelm any health system. The care of such victims would require altered standards of care, including the use of alternative treatment sites such as armories, auditoriums, or gymnasiums. Thus the logistical complexity for planning is clearly daunting, some would say too daunting. However, despite the obstacles, experience from radiation accidents indicates that many victims can be salvaged with appropriate care. The LD_{50} (lethal dose to 50% of persons exposed) for total body irradiation in humans is approximately 3.5–4 Gy without supportive care, but the use of antibiotics and transfusions may increase the LD_{50} to 4.5–7 Gy and survival at doses greater than 10 Gy may be possible with HCT [45]. If a significant fraction of victims with acute injuries could be saved with supportive care alone, appropriate planning and response after a large-scale event could save thousands of people. Thus, a large-scale event will offer extraordinary opportunities for qualified practitioners at large and small centers throughout the United States and potentially internationally to support such an effort. Who would be more qualified than hematologists and oncologists, especially HCT physicians, if properly trained?

Resources for assisting hematologists with clinical management

Acute radiation syndrome (ARS) can affect virtually any organ but primarily manifests as injury to the hematologic, dermatologic, gastrointestinal, and central nervous systems. The severity of ARS increases proportionally with the radiation dose from mild (<1–2 Gy) to invariably lethal (>10–20 Gy). The clinical course of ARS generally includes a prodromal phase, followed by a period of apparent clinical remission, manifest illness, and ultimately recovery or death. Importantly, the latency between exposure and severe manifestations of ARS affords the time to transport victims to RITN sites.

A large fraction of patients with radiation exposure significant enough to induce cytopenias will have multi-organ system damage. Persons exposed to radioactive material may present unique and exceedingly complex management challenges. Few physicians are familiar with the basic manifestations of acute radiation injury or have training in the prospective management of patients with significant radiation exposure. In addition, esoteric aspects of care such as decorporation therapy for internal radiation contamination are extremely important but very few healthcare practitioners have experience in this realm. A number of resources are available to assist with the evaluation and care of radiation exposure victims (Table 38.3). Among these, the Radiation Event Medical Management website (www.remm.nlm.gov) was developed in a collaboration among the National Library of Medicine, Office of the Assistant Secretary for Preparedness and Response, and medical experts from around the world. With assistance from RITN members, REMM includes admission and treatment order templates directed toward victims of radiologic or nuclear events.

To ensure optimal care and enhance preparedness for subsequent events, it is essential that, to whatever extent possible, data on exposure and clinical complications be collected prospectively from victims and compiled centrally. The NMDP has developed a data collection protocol (http://www.RITN.net) for use at RITN centers across the United States. After a large-scale event, centers that accept patients with radiation injury may be asked to contribute patient data to central repositories, either through RITN or governmental agencies.

A role for stem cell transplantation?

Some victims of a large-scale event may receive doses of radiation to cause irreversible myeloablation. As discussed earlier, these patients will commonly have multiorgan damage. What remains unclear is whether allogeneic HCT can be a life-sustaining measure in this setting. To date, 31 patients have undergone allogeneic HCT after accidental radiation exposure. Median survival after transplant for these patients is ∼1 month [4]. All four patients who survived >1 year reconstituted autologous hematopoiesis, raising the question whether the HCT provided any benefit. Particularly troubling was the contribution of GVHD to mortality in >20% of patients. More recently previously unavailable data on the use of stem cell administration to aid recovery of victims of the Chernobyl disaster became available [46]. There were nine patients heretofore unreported in the scientific literature who underwent intraosseous injections of allogeneic bone marrow cells in Kyiv. Transplantation was associated with significantly shortened time to recovery of

granulocyte and platelet counts in these patients. While current guidelines would certainly include the use of cytokines, these data provide an indication of the effectiveness of stem cell transplant to treat victims of radiation exposure.

In many regards, patients with myeloablation from radiation exposure are similar to those with aplastic anemia. A reduced intensity conditioning regimen for severe aplastic anemia (where immunosuppression but not myeloablation is required) is being tested in the Blood and Marrow Transplant Clinical Trials Network (BMT CTN Protocol 0301) [47]. Of note, NMDP has plans in place to conduct large numbers of urgent searches for victims following an event, recognizing that only a few searches would likely lead to transplants.

Current efforts to develop medical radiation countermeasures

Several promising medical countermeasures are under development. However, the complex nature of radiation injury is such that no single drug is likely to provide benefit in all circumstances and against all aspects of radiation injury. Antioxidants and radioprotectants are presumably most effective if present at the time of irradiation, while therapeutics such as a growth factor may target one or more but not all affected organ systems. For this reason, many experts believe that combination therapy will be required to produce substantial improvements in outcomes.

The US Government, particularly the Department of Defense, has a long-standing interest in the development of medical countermeasures against radiation. Beginning in 2005, the Radiation Countermeasures Program at the US National Institute of Allergy and Infectious Diseases (NIAID) has supported the development of medical countermeasures for civilian populations exposed to radiologic or nuclear hazards as a result of accidents or terrorist attacks [48].

Conclusion

Whether a radiologic or nuclear incident occurs domestically or abroad, work continues to ensure that the United States is prepared to assist in planning and response. Many governmental and nongovernmental agencies are involved in the planning. Although the logistical difficulties inherent to any large-scale event are enormous, the potential for life-saving measures is equally large. Future efforts will focus on streamlining these processes, providing training to medical practitioners around the country, and validating medical countermeasures to reduce the morbidity and mortality of radiation exposure. Practitioners and institutions across the country are encouraged to become involved and participate in the planning. The widespread availability of radioactive material has made future exposure events, accidental or intentional, nearly inevitable. Hematologists, oncologists, and HSCT physicians are uniquely suited to care for victims of radiation exposure, creating a collective responsibility to prepare for a variety of contingencies.

Introduction

The field of hematology has had a long and distinguished history, dating back at least to studies of blood by Galen in the years 131–201CE [1]. As our knowledge of the hematopoietic stem (HSC) and progenitor (HPC) cells, and the cytokines and stromal cell populations that regulate the HSC and HPC for production of the blood-forming elements grew [2–5] we learned how to best use this information for therapeutic intervention. Cord blood (CB) hematopoietic cell transplantation (HCT) is an accepted alternative treatment for patients with malignant and non-malignant disorders, with certain advantages compared to bone marrow (BM) and peripheral blood stem cells (PBSC) for HCT. Advantages presented include: ease of collecting the cells which entails little or no risk to the mother or the child, relatively quick access to donor human leukocyte antigen (HLA)-typed CB collections stored as cryopreserved samples in public or family CB banks, and lower stringency HLA matching requirement in unrelated and related transplants compared to BM. Lower stringency in HLA matching is in part due to the relatively naïve state of CB immune cells, and the lesser immune cell-mediated activity that manifests in decreased graft-versus-host disease (GVHD). These advantages of CB have helped recipients to receive a HCT who might not otherwise have a suitable HLA-matched donor. Over 30,000 CB transplants had been performed by 2012 [report of the Bone Marrow Donors Worldwide (BMDW) program] starting with the first HLA-matched sibling CB transplant in October 1988 for Fanconi anemia [6]. The recipient of this first CB transplant is alive and well. However, disadvantages to using CB for transplantation include limiting numbers of total nucleated cells (TNC), and hematopoietic stem (HSC) and progenitor (HPC) cells in CB, which have in part been responsible for increased graft failures. CB HCT is associated with slower time to neutrophil, platelet, and immune cell recovery compared to that for BM or PBSC. Despite this, and counterbalanced by decreased incidence of GVHD, survival has been comparable to that after BM or PBSC transplants. Double CB HCT has extended the use of CB HCT for adults, but has not significantly addressed the issue of delayed cell recovery.

Brief historical perspective of the first CB HCTs

A number of original papers and reviews have been published that highlight the studies that led to the first [6] and subsequent HLA-matched sibling CB HCTs [7–13]. The clinical field of CB HCT was ushered in with the report that HLA-matched sibling CB could be used to save the life of a child with Fanconi anemia [6], a clinical study performed after laboratory studies described CB as a potential source of transplantable HSCs and HPCs [9]. While previous studies had reported the presence of HPCs in CB (reviewed in [9–13]), the critical paper that initiated the concept of using CB in a clinical setting for efficacy [9] demonstrated a number of important points. It was estimated that there would be sufficient cells in a single collection of CB for HCT based on quantities of HPCs in a large number of single CB collections, even though the amount of total nucleated cells per kg recipient body weight would be at least 10-fold less than that used for BM HCT. The high proliferative capacity of CB HPCs compared to those in BM [9] (later described in greater detail [14–16]), was also apparent. In addition, the CB could be maintained in viable form without separation of cells for a few days at room temperature with no obvious loss in HPC viability or numbers. The collected CB cells could be shipped by overnight express mail to a distant laboratory, where they could then be frozen and subsequently thawed months later with a high-efficiency retrieval of functional HPCs [9]. This led to the reality that banks could be set up to store cryopreserved CB cells. High-efficiency recovery after 20-plus years of CB storage has been reported [17]. The first proof-of-principle CB bank was set up in the laboratory of Dr. Broxmeyer, and collections from this bank were used for the first five, and a further two sibling CB HCTs [6,11–13].

Within a few years of these first transplants, sufficient CB HCTs had been done to warrant a report summarizing the effects of sibling CB HCTs [13]. By that time, CB HCT had been extended to treatment of leukemias and other disorders. The first HLA-matched sibling transplant for a child with leukemia using myeloablative conditioning was performed by Dr. John Wagner at Johns Hopkins School of Medicine in Baltimore, MD, USA [12]. The first partially HLA-matched related CB HCTs were reported by Vilmer et al. [18] and Kurtzberg et al. [19]. The patient for the study by Kurtzberg was a 6-year-old African American child with relapsed acute myeloid leukemia (AML) who received a haploidentical related HCT, on February 19, 1993. The patient had previously received an auto transplant (Kurtzberg, personal communication, December 11, 2012). The first bank to store and provide unrelated CB units for

HCT was started by Dr. Pablo Rubinstein at the New York Blood Center, New York, NY, USA [20,21]. The first unrelated, and many subsequent unrelated CB HCTs, were performed by Dr. Joanne Kurtzberg at the Duke University Medical Center using CB units obtained from the New York Blood Center bank.

CB banking

It was recognized early on, and prior to the first CB HCT, that CB could be frozen in a cryopreserved state, with efficient recovery of viable and functional HPC after thawing months to years later (reviewed in [17]). The outstanding engraftment potential of HSC, assessed by isolating $CD34^+$ cells from unseparated populations cryopreserved more than 20 years previously and assaying their engrafting capability in mice with non-obese diabetic, severe combined immunodeficiency, and with a gene deletion in the interleukin (IL)-2 receptor gamma chain [17], was also acknowledged (Figure 39.1). Currently, both public and private (e.g., family-directed) CB banks exist, but the overwhelming majority of CB units used for HCT have come from the public CB banks. Regardless, there is a clear necessity for both types of CB banks to operate under the highest level of regulatory standards [22]. A number of recent

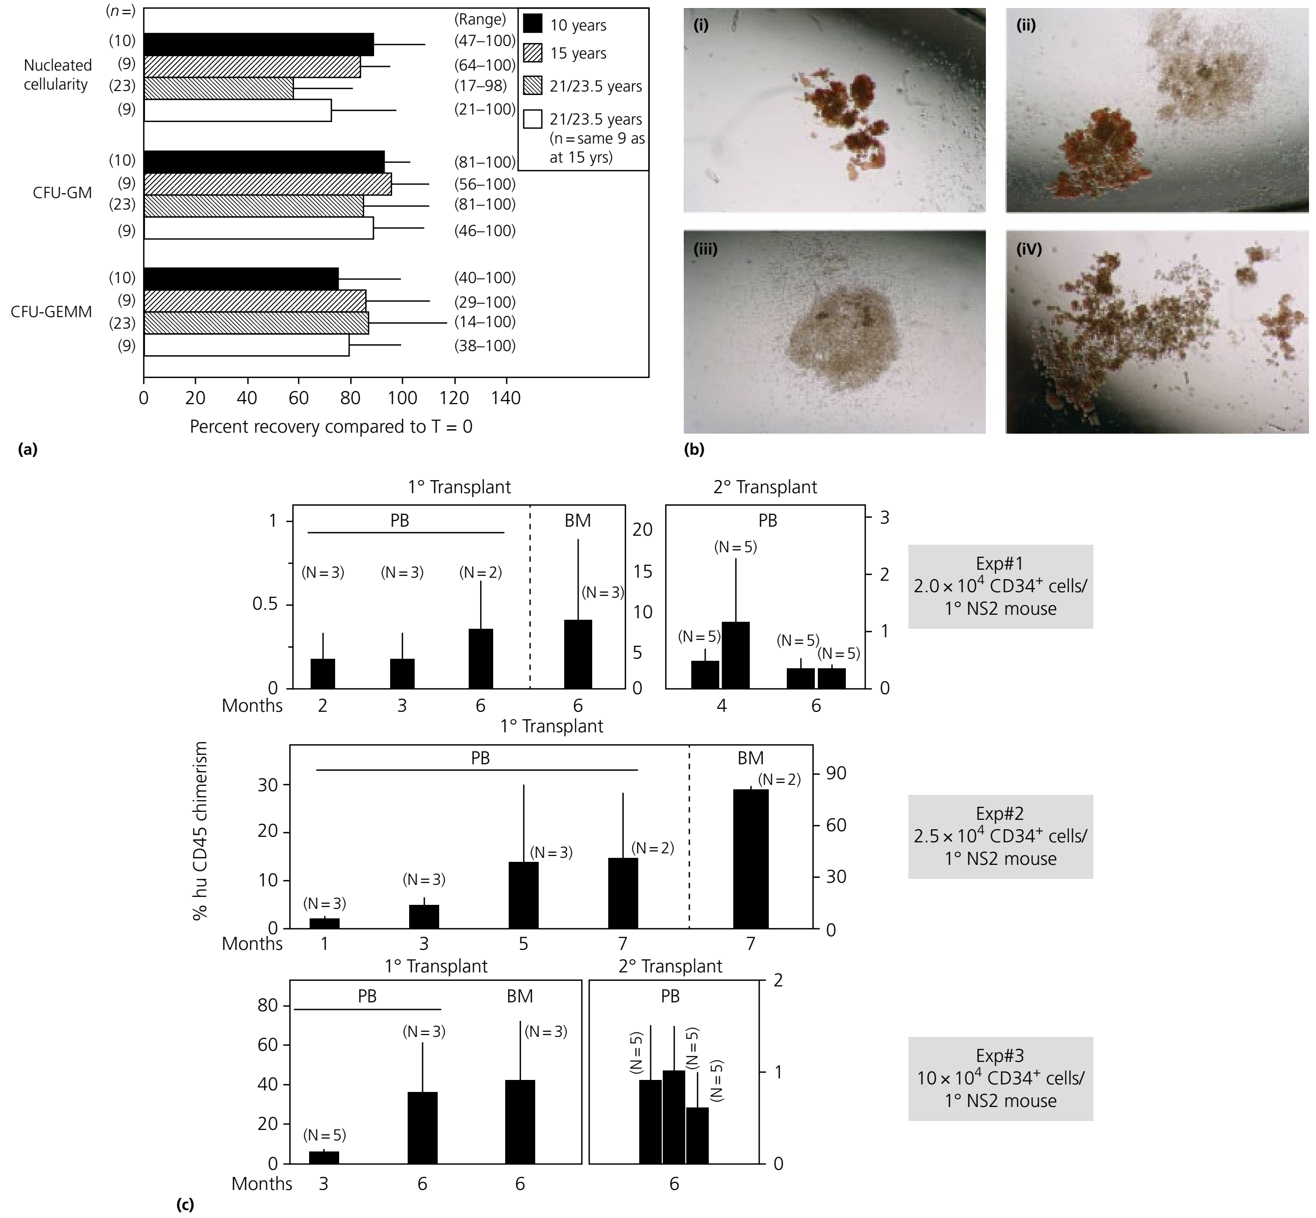

Figure 39.1 Recovery of cells after thawing of unseparated CB stored frozen for over 20 years. (a) Comparative percent recovery of nucleated cells, granulocyte macrophage (CFU-GM), and multipotential (CFU-GEMM) progenitor cells after 10, 15, and 21/23.5 years of cryopreserved storage. (b) Representative examples of colonies grown from CB thawed after 21–23.5 years in frozen state: (i) CFU-GEMM colony; (ii) CFU-GEMM (left) and CFU-GM (right) colonies; (iii) CFU-GM colony; (iv) CFU-GEMM colony. (c) Engraftment of $CD34^+$ CB cells (isolated from unseparated cells stored frozen for more than 20 years) in primary and secondary HCT in sublethally irradiated NOD/SCID IL-2 receptor gamma chain null mice. Three different experiments shown, each with a different frozen CB unit. Source: Broxmeyer et al. 2011 [23]. Reproduced with permission of the American Society of Hematology.

reviews have highlighted the development and application of CB banking processes, standards, regulations, and the accreditation of the banks [23–25], as well as the process for CB search and distribution [26], and the management of the units of CB to be used for HCT at the transplant center [27]. There are now CB banks in both developing and developed countries [28]. Most banks cooperate through international registries that list publicly banked CB units in searchable databases such as the BMDW program, the NetCord Foundation, the National Marrow Donor Program (NMDP), and other national registries. International accreditation bodies, and governmental regulatory requirements are in place to assure that publicly available CB units meet strict rules for quality [25,29,30]. Outcome data are collected and are available for analysis through international data registries that allow monitoring and analysis of CB HCT activity and outcomes.

Clinical results

Related or familiar CB for allogeneic HCT in children

Approximately 700 sibling HCT cases have been performed in Europe, most reported to the Eurocord registry (V. Rocha, personal information). Of these, around 150 children have received CB cells in association with BM cells from the same donor, due to low CB cell numbers at collection. Numbers of related CBTs have not increased year to year. Most recipients were children, and all but 29 were completely HLA matched. Table 39.1 lists the diagnosis of children transplanted with an HLA-identical sibling CB. Among 519 recipients of HLA-matched CB with available information on outcomes, 4-year overall survival was 91% for patients with non-malignant diseases and 56% for patients with malignant diseases. The cumulative incidence (CI) of neutrophil engraftment was 91% with a median time of 22 days (range 12–80 days). The number of CD34$^+$ cells infused was associated with engraftment, which was 95% if CD34$^+$ cell counts were greater than 1.4×10^5/kg and 90% if the counts were less ($p = 0.02$). The CI of acute and chronic GVHD at day 100 and at 4 years was 12% and 13%, respectively (V. Rocha for Eurocord, unpublished data).

To compare outcomes after CB HCT with BM HCT in the HLA-identical setting, Eurocord in collaboration with the International Bone Marrow Transplant Registry (IBMTR) evaluated 113 HLA-identical sibling CB HCTs in which the patients were transplanted from 1990–1997, and compared them to 2052 HLA-identical sibling BM HCTs carried out during the same period [31]. This comparative analysis demonstrated lower risks of acute and chronic GVHD, but delayed neutrophil recovery after CB compared to BM HCT. Survival was similar for both malignant and non-malignant disorders. Although the mechanism of such GVHD reduction is not fully understood, the immunologic immaturity of the newborn, the lower number of T cells in the graft, and the enrichment of CB regulatory T (Treg) cells as well as other immune cells within CB may account at least in part for this phenomenon. These lesser GVHD results were in part used as the basis for advocating HLA-mismatched CB HCTs and for further development of unrelated CB banks.

Related CB for malignant disorders

Risk factors and long-term outcomes have been reported for 147 HLA-identical sibling recipients with hematologic malignancies [32]. Median follow-up was 6.7 years. Median patient's age was 5 years. Acute leukemia was the most frequent diagnosis (74%). In brief, higher cell dose, not using MTX in GVHD prophylaxis, and disease remission, are the main factors influencing outcomes after related HLA-identical CB HCT.

Table 39.1 Diagnosis of children transplanted with HLA identical sibling CB

Diagnosis	**Number of patients (%)**

Histiocytosis	4 (1)
Other diagnosis	5 (1)

Abbreviations: ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; MDS, myelodisplastic syndrome; MPN, myeloproliferative neoplasm; CML, chronic myelogenous leukemia; CLL, chronic lymphocytic leukemia; BMF, bone marrow failure syndrome; CGD, chronic granulomatous disease; SCID, severe combined immune deficiency.

Most related CB HCTs are performed in children with genetic diseases such as hemoglobinopathies [thalassemia major (TM), or sickle cell disease (SCD)] and genetic bone marrow failure syndromes (BMFS; with the majority being Fanconi anemia) (Table 39.1). Forty-four patients (median age 5 years, range 1–20) given a CB HCT for either TM ($n = 33$) or SCD ($n = 11$) were analyzed [32]. No patient died and 36 out of 44 children remained disease-free with a median follow-up of 24 months (range 4–76). Only 4 patients experienced grade II acute GVHD; only 2 out of the 36 patients at risk developed limited chronic GVHD. The 2-year probability of DFS was 79% and 90%, respectively, for patients with TM and SCD. Use of MTX for GVHD prophylaxis was associated with an increased risk of treatment failure. More recently, long-term outcomes were determined in 485 patients with TM or SCD who were treated by either HLA-identical sibling CB HCT ($n = 96$) or BM HCT ($n = 389$) (V. Rocha for Eurocord group, unpublished data). In comparison with patients receiving BM ($n = 259$ for TM; $n = 130$ for SCD), those given CB ($n = 66$ for TM; $n = 30$ for SCD) had slower neutrophil recovery, decreased incidence of acute GVHD and none had extensive chronic GVHD. With a median follow-up of 70 months, 6-year OS was 95% and 97%, respectively, after BM and CB. The 6-year DFS was 86% and 80% in patients with TM after BM and CB, respectively, while DFS in SCD patients was 92% and 90%, respectively. In a multivariate analysis, DFS was not statistically different between CB and BM HCT recipients. In summary, patients with TM or SCD had excellent outcomes after both CB and BM HCT from an HLA-identical sibling. However, in these cases CB may be preferable over BM because of the lower incidence of chronic GVHD and no harm to the donor.

Table 39.2 Advantages and limitations of unrelated donor BM, CB, and haploidentical cells from a relative, and main criteria to be considered for choosing an alternative donor for patients without an HLA-identical sibling

	Unrelated-HCT	CB-HCT	Haplo-HCT
Information on A+B+DRB1 (DNA) typing	16–56%	~80%	100%
Median search time	3–6 months	<1 month	<1 month
Donors identified but not available	20–30%	~1%	None
Rare haplotypes represented	2–10%	20–40%	Non-applicable
Main limiting factor to graft acquisition	HLA identity	Cell dose for single CB	Poor mobilization of HSCs

Directed donor CB banking

A number of studies have reported on efforts to systematically identify, collect, and store CB units for family-directed use [22,32,33] or for research that investigates the use of autologous CB cells, also for using those cells for gene therapy. Care must be taken to ensure that such CB banks meet the necessary critical criteria needed to store these units [22]. Recent surveys on directed family cord blood banking have been published by Eurocord, NetCord, the NMDP, and others [22,23]. The successful use of family banked CB to treat patients was reported [34–36], although the probability of using an autologous CB is very low (4 per million). Whether or not to bank a child's CB for autologous or family use is a personal decision, based on informed knowledge.

Clinical use of unrelated CB cells for allogeneic HCT

The first public CB bank was established in 1991 [37], and the first unrelated CB HCT was performed in 1993 for a 4-year-old child with leukemia [38]. There are substantial logistic and clinical advantages to the use of CB in the unrelated setting particularly for underrepresented minority and mixed ethnicity patients who often cannot identify a suitably matched related or unrelated donor. Table 39.2 lists the advantages and disadvantages of CB compared with alternative sources of donor cells for unrelated or HLA-mismatched family members and patients lacking a HLA sibling HCT donor.

CB HCT has been marked by improved outcomes, especially in adults, as knowledge of TNC dose requirements led to improved collection, and to availability of CB units with higher cell doses. Improvements in supportive care have also contributed. The use of double CB HCT [39] opened up CB HCT for essentially all patients without suitable donors. However, double CB HCT does not result in faster neutrophil, platelet, or immune cell recovery.

Unrelated CB HCT in children

Unrelated donor CB HCT in children has been carried out for a multitude of disorders (Table 39.3), and results are comparable to other sources of HSCs [40–42]. For metabolic diseases and primary immunodeficiencies, CB cells is considered a preferable source of HSCs for transplantation. Results of the first prospective phase II multicenter trials on unrelated CB transplantation (COBLT) for children with hematologic malignancies [43] noted that the CI of neutrophil recovery, acute GVHD, chronic GVHD, and relapse were 80%, 20%, 21%, and 20%, respectively. Two-year overall survival was 49.5%. Risk factor analysis for outcome was associated with cell dose, HLA disparities, ABO compatibility, patients' CMV positivity, disease, and disease status at transplantation. Outcomes of CB HCT in children have been reported for acute lymphoblastic leukemia (ALL) [42], acute myeloid leukemia (AML) [43], myelodysplastic syndrome (MDS) [44], Hurler syndrome [45], Krabbe disease [46], Fanconi anemia [47], and primary immunodeficiencies [48]. Figure 39.2 shows the overall 2-year survival for 3546 children with malignant (*n* = 2163) and non-malignant (*n* = 1383) disorders transplanted with an unrelated CB graft and reported to Eurocord.

Malignant hematologic diseases

Children with ALL

About 20–30% of children with ALL will need to be treated with an allogeneic HCT, either because of very poor prognostic factors at diagnosis or following relapse. Children with ALL (*n* = 532) were retrospectively analyzed in first (1st) complete remission (CR) (*n* = 186), 2nd CR (*n* = 238), 3rd CR, or advanced disease patients (*n* = 108) who received CB cells as a first transplant. The most common immunophenotype was B-cell precursor ALL; 17 patients had biphenotypic ALL. Of 186 patients transplanted in 1st CR, poor risk cytogenetic [t-(4;11) and t-(9;22)] was present in 40%. Most of the CB grafts were single units, HLA 5/6 and 4/6, and median TNC dose infused was 4 × 10^7/kg. Cumulative Incidence (CI) of neutrophil recovery, acute GVHD, and transplantation-related mortality (TRM) was 82%, 27%, and 21%, respectively. In multivariate analysis, TNC infused (>4 × 10^7/kg), and remission status at time of CB HCT were associated with improved neutrophil recovery. The CI of

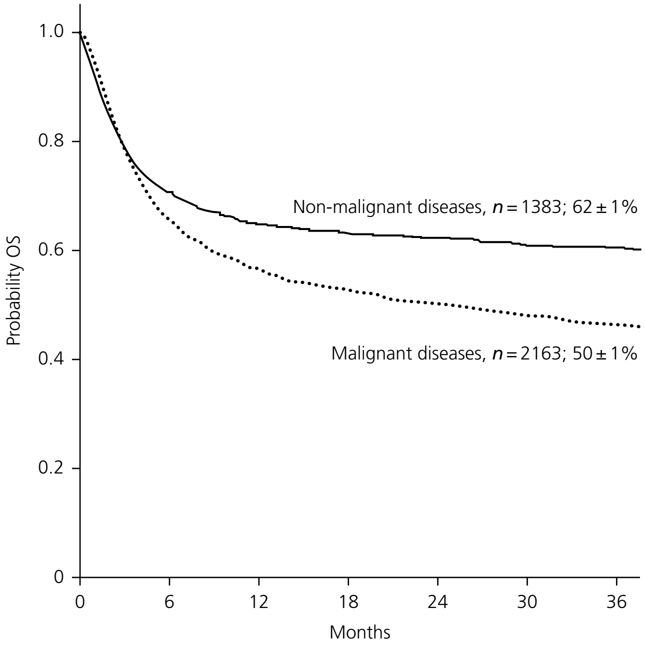

Figure 39.2 Two-year survival in children given an unrelated single CB HCT based on non-malignant and malignant disease state.

2-year relapse was 37% (31% for 1st CR, 34% for 2nd CR, and 50% for more advanced disease). In multivariate analysis, disease status at CB HCT and use of total body irradiation (TBI) were independently associated with lower CI of relapse. The 2-year probability of leukemia-free survival (LFS) was 38% (49% for 1st CR, 42% for 2nd CR, and 10% for more advanced disease). To address the prognostic value of minimal residual disease (MRD) before CB in children with ALL, 170 ALL children transplanted in CR after myeloablative conditioning regimen were analyzed [49]. At 4 years, CI of relapse was 30%, incidence being lower in patients with negative minimal residual disease (MRD) before CB HCT when compared to those with a positive MRD (24% vs. 39%; $p = 0.05$). There was also an impact of MRD on LFS. LFS was 54% when patients with negative MRD were transplanted compared to 29% for those patients with a positive MDR before CB HCT ($p = 0.003$). Thus, MRD assessment before CB HCT allows identification of patients at higher risk of relapse after transplantation.

Children with AML

Eurocord published results of CB HCT for childhood AML [43]. A cohort of 95 children was analyzed. LFS was 59% in children transplanted in 1st CR, 50% in 2nd CR, none among 5 in 3rd CR or beyond, and 21% for children transplanted in relapse. The results of CB were particularly encouraging for AML with a poor karyotype. With the aim to assess the impact of cytogenetic and molecular markers on outcomes after CB HCT for children with AML, 390 children transplanted from 1994 to 2010 were studied. At the time of transplantation, 37% were in 1st CR, 42% in 2nd CR, and 21% had more advanced disease. The majority of children had either one (44%) or two (37%) HLA disparities out of six with their graft. Median infused TNC and CD34 cells dose were respectively 4.95×10^7/kg and 1.9×10^5/kg. The majority of patients (86%) received myeloablative conditioning (MAC). The CI of neutrophil recovery was 85% and was associated with TNC and CD34$^+$ cell dose infused. At day 100, the CI of grade II–IV acute GVHD was 34%. At 1 year, the CI of non-relapse mortality was 24% and this was associated with the TNC dose ($>4.9 \times 10^7$/kg) and disease status. At 2 years, the probability of LFS was 63% in 1st CR, 43% in 2nd CR, and 22% in more advanced patients. LFS of 49 children transplanted in 1st CR with unfavourable disease was 70%, not statistically different from the overall 1st CR group. For CB HCT in 2nd CR, LFS was 71%, 33%, and 40% in the favorable, intermediate, and unfavorable subgroups, respectively. Multivariate analysis for 2nd CR cohort identified two significant prognostic factors: favorable disease subgroup ($p = 0.005$) and duration of previous CR longer than 7 months ($p = 0.03$) (V. Rocha for Eurocord, unpublished data).

CB HCT for children with MDS and juvenile myelomonocytic leukemia (JMML)

There are few reports investigating the outcome of children with MDS given an unrelated donor HCT. Most of these reports are limited to a small and heterogeneous series of studies [50,51] for JMML and/or secondary AML, including adult recipients in those reports [52,53]. In a collaborative study between the European Working Group on childhood MDS (EWOG-MDS), CIBMTR, and Eurocord–EBMT, factors were examined that influence the outcome of 70 children with MDS (refractory cytopenia ($n = 33$), refractory anemia with excess blasts ($n = 28$), and refractory anemia with excess blasts in transformation ($n = 9$) at diagnosis), who received a CB HCT after receiving a myeloablative regimen [44]. At day +60, the probability of neutrophil recovery was 76%; with a TNC $> 6 \times 10^7$/kg, transplantation of HLA-matched or 1-locus-mismatched CB cells and an irradiation-containing conditioning regimen favoring faster engraftment. The overall 3-year probability of DFS was 39%. It was 66% when HCT was performed within 6 months from diagnosis, as compared to 20% for patients grafted after a longer interval from diagnosis. TRM was lower in children receiving an allograft after the year 2001.

In a separate analysis, outcomes and risk factors were studied for 110 children with JMML, given a first single unmanipulated CB HCT from 1995 to 2010 (V. Rocha for Eurocord and CIBMTR, unpublished data). Monosomy of chromosome 7 was the most frequent cytogenetic abnormality (24%). Nineteen percent of CB units were HLA-identical or 6/6 (antigen level for HLA-A and -B, allelic for DRB1), while 43% and 38% had 5/6 or 3/6 compatibilities. At 60 days after CB HCT, the CI of neutrophil recovery was 80%, with a median time of 25 days. The CI of grade II–IV acute GVHD was 40% at 100 days. At 4 years, the CI of relapse was 37%; children who were older than 1 year at diagnosis were independently associated with increased relapse. At 4 years, DFS was 43%. In multivariate analysis, factors associated with improved LFS were: age younger than 1 year at diagnosis, graft with a 6/6 or 5/6 HLA CB unit, and absence of monosomy 7.

CB HCT outcomes compared with unrelated donor cells in children with acute leukemia

Comparison of results of CB and BM HCT from unrelated donors in children is of paramount relevance, because for many patients the search process will identify both CB units and BM donors. Briefly, recipients of CB were transplanted sooner compared to children given BM; neutrophil and platelet recovery were delayed, acute GVHD was decreased, and OS was not significantly different after CB compared to BM HCT [40]. Since 1998, the choice of an unrelated donor has been based on HLA high resolution typing of class I and II. For this reason, a study has compared the outcomes of 503 children with acute leukemia given CB versus 282 BM recipients transplanted with grafts that were matched for allele level for HLA-A, HLA-B, HLA-C, and HLA-DRB ($n = 116$), or mismatched ($n = 166$) [41]. Recipients of CB were transplanted with grafts that were HLA matched ($n = 35$) or HLA mismatched for one ($n = 201$) or two antigens ($n = 267$) out of six. In comparison with allele-matched BM transplants, 5-year LFS was similar to that after transplants of CB mismatched for either one or two antigens. TRM rates were higher after transplants of two-antigen HLA-mismatched CB and possibly after one-antigen HLA-mismatched low-cell-dose CB transplants. Relapse rates were lower after two-antigen HLA-mismatched CB transplants. These data strongly suggest that CB is an acceptable alternative to HLA-matched unrelated BM in children and support the concept of starting a simultaneous search for BM and CB unrelated donors. The final selection of unrelated donor BM versus CB should be based on the urgency of the transplant, and characteristics of the BM and CB unrelated donor such as cell dose availability and HLA compatibility.

Non-malignant hematologic diseases

Among the congenital bone marrow failure syndromes (BMFS), Fanconi anemia is the most frequent indication for allogeneic HCT. The outcomes of CB HCT in 72 patients with Fanconi anemia were reported [47]. Outcomes of CB HCT were analyzed in 44 patients with other congenital BMFS [54]. Diagnosis was: Diamond-Blackfan anemia, amegakaryocytic thrombocytopenia, dyskeratosis-congenita, Shwachman–Diamond syndrome, Kostmann disease, agranulocytosis, and unclassified BMFS. The majority of the grafts were HLA mismatched and three patients received double CB HCT. Median TNC infused was 6.1×10^7/kg. Day 60 CI of neutrophil recovery was 55%, 100-day CI of acute GVHD (grade II–IV) was 24%, 2-year CI chronic GVHD was 53%. Improved OS was associated with age <5 years and number of infused TNC $\geq 6.1 \times 10^7$/kg. In both analyses cited above a higher incidence of graft failure was observed [47,54]. Outcomes after CB HCT for patients with BMFS can be improved by selecting units more closely HLA matched and with higher cell dose. In addition, the use of more immunosuppressive drugs such as fludarabine in the conditioning regimen and the avoidance of MTX in the GVHD prophylaxis may also improve engraftment and survival.

Allogeneic HCT is considered an effective treatment to prevent disease progression for patients with metabolic disorders, with Hurler syndrome being the most common disease in this setting. The 3-year event-free survival (EFS) and 3-year OS rates were 70% and 77%, respectively, after CB HCT in 93 children [45]. More recently, outcomes were compared after HCT in 258 children with Hurler syndrome according to graft source and donor type (V. Rocha for Eurocord, EBMT, and CIBMTR, unpublished data). OS and EFS at 5 years, were 74% and 63%, respectively, after HCT. However, EFS after HLA-matched sibling donor and 6/6 HLA-matched unrelated CB HCT were similar at 81%. It was 66% after 10/10 HLA-matched unrelated donor and 68% after 5/6 matched CB HCT. EFS was lower after transplantation of 4/6 matched CB cells (57%; $p = 0.031$), than after HLA-mismatched unrelated donors 41% EFS ($p = 0.004$) and T-cell depleted unrelated donor (36%; $p = 0.005$). Full donor chimerism and normal enzyme levels were higher after CB HCT (92% and 98%, respectively) compared to the other grafts sources and donors (69% and 59%, respectively). Results of allogeneic transplantation for Hurler syndrome are encouraging with similar EFS rates after matched sibling donors, 6/6 matched unrelated CB, 5/6 unrelated CB, and 10/10 matched unrelated donors. The use of mismatched unrelated donors and 4/6 matched unrelated CB was associated with lower EFS.

CB HCT has been successfully used in children with various primary immunodeficiencies [48,55]. Since severe primary T-cell immune deficiencies are pediatric emergencies, immediate HSC donors are mismatched related donor (MMRD) or CB HCT, in the absence of an HLA-identical sibling donor. Recently, 175 MMRD HCTs were retrospectively compared with 74 CB HCTs performed in 32 transplant centers [55]. T-cell depletion was used in all MMRD HCT. T-cell engraftment was not statistically different between the two groups. CB recipients had a higher frequency of complete donor chimerism at day 100 and faster total lymphocyte recovery compared to MMRD recipients, and independence of immunoglobulin replacement therapy was achieved faster and more frequently after CB HCT. Estimated 5-year OS was 62% after MMRD and was 57% after CB HCT. In the CB group, OS rate was improved in the group of patients with severe combined immunodeficiency given a CB graft with an HLA-identical 6/6 (76%; $n = 21$) or 5/6 (62%; $n = 29$ match) compared to 4/6 HLA disparities (35%; $n = 24$).

Outcomes after HLA-matched unrelated donor HCT for TM have been reported with encouraging results, but larger series of patients with longer follow-up are needed to draw definitive conclusions [56]. The use of unrelated HCT for TM and SCD is still controversial, and its efficacy is under evaluation in clinical protocols. A recent phase II study in the United States, evaluating the use of CB HCT after reduced intensity conditioning (RIC) regimen in 8 children with SCD resulted in suspended recruitment due to high incidence of graft failure [57]. The Eurocord group in collaboration with CIBMTR retrospectively examined the efficacy of CB HCT in children with TM ($n = 35$) and SCD ($n = 16$) [58]. Donor–recipient pairs were matched at HLA-A and -B (antigen level) and DRB1 (allele level) in 7, or HLA mismatched at one ($n = 18$), two ($n = 25$), or three loci ($n = 1$). Transplant preparative regimen was MAC ($n = 39$) or RIC ($n = 12$). Neutrophil recovery with donor chimerism was documented in 24 patients; 11 patients developed grade II–IV acute GHVD, and 10 patients developed chronic GVHD. OS and DFS was 62% and 21% for TM and 94% and 50% for SCD, respectively. In multivariate analysis, engraftment rate and DFS were improved with a CB unit containing a TNC dose $>5 \times 10^7$/kg. The 2-year probability of DFS was 45% in patients who received grafts with cell dose $>5 \times 10^7$/kg and 13% with lower cell doses. Novel approaches aimed at improving engraftment will be needed before unrelated CB HCT can be widely adopted for transplanting patients with TM and severe SCD.

Unrelated CB HCT in adults

Numbers of adult CB HCTs have increased and since 2006 adults have surpassed the numbers of children being transplanted with CB. This increase is mainly due to: (i) similar outcomes of CB HCT to that of HLA-matched BM or MPB donors, (ii) double CB units to circumvent problems of cell dose, and (iii) reduced-intensity conditioning regimens that decrease TRM. Most CB HCTs are performed in adults with malignant disorders using double cord blood units.

Adults with ALL

Single center experience has shown interesting results in CB HCT in adult recipients with high-risk ALL, but reports analyzed a small series of patients. One [59] described 22 patients who received reduced-intensity conditioning regimen (RIC) followed by allogeneic transplantation with either matched related ($n = 4$) or CB ($n = 18$) donor grafts. OS, TRM, and relapse were 50%, 27%, and 36% at 3 years, respectively. Another published results on 27 patients receiving single CB HCT after myeloablative conditioning (MAC) [60].

With a median follow-up of 47 months, the probability of LFS at 5 years was 57%. A more recent study reported outcomes after CB HCT for 256 adults with ALL transplanted from 1997–2006 in Japan [61]. The CI of neutrophil engraftment at day 100 was 78%. Infused CD34$^+$ cell dose ($>1 \times 10^5$/kg) was associated with successful neutrophil engraftment. CI of grade II–IV acute GVHD at day 100 was 37%. Two-year LFS and OS rates were respectively 36% and 42%. Multivariate analysis showed that in patients older than 51 years, active disease at time of the CB HCT, presence of grade III–IV acute GVHD, and absence of chronic GVHD were negatively associated with OS.

The Eurocord group has performed a survey and risk factor analysis of outcomes after CB HCT for adults with ALL (V. Rocha for Eurocord, unpublished data). From 2000 to 2011, 421 adult patients received a CB HCT for ALL in European centers. Median age at time of CB HCT was 32 years (18 to 76 years) and 59% of patients (n = 247) were older than 35. At time of transplant 46% (n = 195) were in 1st CR, 32% (n = 136) in 2nd CR, and 22% (n = 90) of patients were not in remission. Of 314 patients with available karyotype at diagnosis, 229 had abnormalities. Double CB HCT was performed in 173 patients (41%). Most patients received CB units with one (24%; n = 103) or two (55%; n = 231) HLA disparities. MAC was given to 314 patients (75%), and 103 patients (25%) received RIC. Median follow-up was 27 months. The CI of 60-day neutrophil recovery was 78%. CI of acute and chronic GVHD was 33% and 26%, respectively. CI of TRM at 2-years was 42% and was lower in patients <35 years in CR at transplant and using RIC. Two-year RI was 28% and the factors associated with lower RI were use of MAC, and CR at the time of transplant. Estimated 2-year LFS was 39% for patients in 1st CR (n = 195), 31% for 2nd CR (n = 136), and 8% for advanced disease (n = 90). Three factors were associated with improved LFS: age <35 years, CR at transplant, and not using antithymocyte globulin as part of the conditioning regimen. In patients with Ph+ ALL (n = 129), 2-year CI of TRM and relapse were 35% and 28%, respectively, and 2-year LFS was 36%. As shown in children [49], presence of MRD before CB HCT was also associated with final outcomes in adult CB HCT recipients. Sixty-five patients with Ph+ ALL in remission were analyzed for whom a MRD was performed before CB HCT (34 were positive and 31 were negative). LFS at 2 years was 48% for those patients transplanted with a negative MDR and 38% for those with a positive MRD ($p = 0.05$) (V. Rocha for Eurocord, unpublished data). Thus, CB HCT for patients with ALL is an alternative option for those without an HLA-identical sibling.

Adults with AML

In spite of reports and retrospective comparisons with other HSC sources, reports on outcomes and risk factor analysis on larger series of AML patients given CB HCT with longer follow-up and more homogenous populations are still missing. Some single center experiences and registry data have reported encouraging results [62–65]. LFS varied from 40% to 46% in 1st CR, from 26% to 39% in 2nd CR, and from 11% to 20% in advanced phase of the disease.

Eurocord conducted a survey on outcomes of CB HCT for adults with AML. Adult patients (n = 604) with de novo AML in 1st CR (n = 229), 2nd CR or 3rd CR (n = 228), and advanced disease (n = 147) who received CB HCT as a first transplant were retrospectively analyzed (V. Rocha for Eurocord, unpublished data). CB HCT was performed from 2000–2010 in 131 European centers. Median age of recipients was 41 years, and 18% of the patients had previous autologous transplants. Based on available cytogenetic and molecular markers at diagnosis (n = 339), 56% were in intermediate risk and 31% in unfavorable risk groups. Grafts were single (n = 361) or double (n = 243) CB units; 39% of CB units were identical to recipient or had 5/6 HLA matched (antigen level for HLA-A and -B allelic level for DRB1), while 61% had 4 or 3/6 HLA compatibilities. At infusion median, TNC dose was 3.1×10^7/kg (2.4×10^7/kg with single CB and 3.7×10^7/kg with double CB) and median CD34$^+$ cell count was 1.2×10^5/kg (1×10^5/kg with single and 1.3×10^5/kg with double). MAC was given to 51% and RIC to 49% of recipients. The most common regimens used were busulfan in combination with fludarabine and thiotepa for MAC, and cyclophosphamide plus fludarabine and TBI 2Gy for RIC. GVHD prophylaxis consisted of cyclosporine A (CSA) associated or not with mycophenolate mofetil (MMF) treatment in 58% and CSA ± corticosteroids in 32% of patients. Median follow-up was 13 months. The CI of neutrophil recovery, acute GVHD (II–IV) and 1-year TRM was 80%, 26%, and 21%, respectively. CI relapse at 2 years was 38% (1st CR 27%, 2nd CR and 3rd CR 29%, and non-remission 56%); it was 31% for those patients transplanted with MAC (n = 291) and 30% with RIC (n = 282). For patients given MAC, 2-year LFS was 50% for 1st CR, 27% for 2nd CR and 3rd CR, and 17% for those patients transplanted in non-remission, whereas it was 35%, 44%, and 18% for RIC, respectively. In this large series of patients, but still short follow-up time, CB HCT appears to be an option for treatment of adults with high-risk AML after MAC or RIC without an HLA-identical donor.

Adults with MDS

Reports of CB HCT for patients with MDS have been scarce [66–68]. Through Eurocord and EBMT registries, outcomes and risk factors have been evaluated for adult patients who underwent single or double CB HCT for MDS or secondary AML [69]. Adults with MDS (n = 39) or secondary AML (n = 69) were analyzed. Median age was 43 (18–72) years. Seventy-seven patients (71%) received a single CB HCT. MAC was given to 57 (53%) patients. Median numbers of nucleated and CD34$^+$ cells at freezing were respectively, 3.6×10^7/kg and 1.1×10^5/kg. At 60 days, CI of neutrophil recovery was 78% and was independently associated with numbers of CD34$^+$ cells/kg ($>1.1 \times 10^5$/kg) and advanced disease status (blasts <5% at time of CB HCT). Two-year non-relapse mortality (NRM) was significantly higher after MAC (62% vs. 34%; $p = 0.009$). Two-year DFS and OS were 30% and 34%, respectively. In multivariate analysis, patients with high-risk disease (blasts >5% and international prognostic scoring system, intermediate-2 or higher) had significantly poorer DFS. Neutrophil recovery seemed inferior to that in other malignant disorders in adults, and a CB unit containing a high number of CD34$^+$ cells or a double CB HCT should be recommended. DFS of 30% appears to be comparable to that after HCT using other sources of donor cells in large multicentric studies in high-risk MDS patients. No retrospective comparisons with other sources of donor cells have been made in this disease-specific setting.

Adults with lymphoid malignancies

There have been some reports of CB HCT for refractory non-Hodgkin lymphoma (NHL) [70–72] and malignant lymphoma treated by RIC-CB HCT [73,74]. The Eurocord group evaluated 104 adult patients (median age, 41 years) who underwent unrelated donor CB HCT for lymphoid malignancies [75]. The CI of neutrophil engraftment was 84% by day 60, with greater engraftment in recipients of higher CD34$^+$/kg cell dose. CI of TRM was 28% at 1 year, with a lower risk in patients treated with low-dose TBI. CI of relapse or progression was 31% at 1 year, with a lower risk in recipients of double-unit CB HCT, and those with chemosensitive disease. The probability of DFS was 40% at 1 year, with improved survival in those with chemosensitive disease (49% vs. 34%), who received higher cell doses ($\geq 2 \times 10^7$/kg) (49% vs. 21%) and conditioning regimens containing low-dose TBI (59% vs. 23%). Thus, CB HCT is a viable treatment for adults with advanced lymphoid malignancies. Several important strategies to be considered for patients with malignant lymphoma and CLL are: greater use of less toxic RIC regimens, such as those containing low-dose TBI, better selection of CB units, and broader use of double CB HCT.

Results of unrelated CB

Adults with acute leukemia and other hematologic malignancies after myeloablative conditioning regimen

Currently the choice of unrelated donor is based on high-resolution typing or allelic typing for HLA-Class I and II. Therefore, Eurocord in collaboration with CIBMTR compared results of unrelated CB HCT in adults with acute leukemia, given a CB graft (with more than 2.5×10^7/kg TNC at freezing and not more than 2 out of 6 HLA disparities), with BM or PB grafts (allelic typing for HLA-A, -B, -C, -DRB1) after MAC. Data were available on 1525 patients aged >16 years with acute leukemia transplanted between 2002 and 2006 using CB ($n = 165$), PBSC ($n = 888$), and BM ($n = 472$) [76]. CB units were matched at HLA-A and -B at an antigen level and -DRB1 at an allele level ($n = 10$), or were mismatched for one ($n = 40$) or two antigens ($n = 115$). PBSC and BM grafts from unrelated adult donors were matched for allele-level HLA-A, -B, -C, -DRB1 ($n = 632$; $n = 332$) or mismatched at one locus ($n = 256$; $n = 140$). LFS after CB HCT was comparable to that observed after allele-matched (at HLA-A, -B, -C, -DRB1) and mismatched PBSC or BM transplantation. TRM was higher after CB HCT than after allele-matched MPB ($p = 0.003$) or BM ($p = 0.003$), since the engraftment rate was decreased in CB recipients. Grades II–IV acute and chronic GVHD were lower in CB HCT recipients compared to allele-matched MPB ($p < 0.001$ and $p < 0.001$, respectively). Chronic, but not acute GVHD, was lower after CB compared to allele-matched BM HCT ($p = 0.011$). Therefore a search for CB units is recommended in absence of an HLA-matched or single antigen-mismatched donor, or in urgent situations when time to search for a donor is limited.

Adults with lymphoid malignancies after RIC HCT compared to unrelated PBSC

The Eurocord group in collaboration with the Lymphoma Working Party of EBMT studied 645 adult patients with lymphoid malignancies who received a single or double CB HCT ($n = 104$) or a mismatched unrelated donor (MUD) HCT ($n = 541$) after a RIC regimen (V. Rocha for Eurocord, unpublished data). Median follow-up time was 30 months. The CI of engraftment at day 60 was 81% after CB and 97% after MUD HCT, whereas at day 100, the CI of grade II–IV acute GVHD was 29% and 32%, respectively. At 36 months, the CI of TRM was 29% after CB and 28% after MUD HCT, relapse or progression was 28% and 35%, and chronic GVHD was 52% and 26% ($p < 0.01$), respectively. Two-year progression-free survival (PFS) and OS were 43% and 58% after CB and 36% and 51% after MUD HCT, respectively. In a multivariate analysis, TRM, relapse or progression, PFS and OS were not statistically different between CB and MUD HCT, but MUD HCT was associated with higher risk of chronic GVHD and CB HCT with delayed engraftment. Thus, CB HCT is a valuable alternative for patients with advanced lymphoma and CLL who lack an HLA-matched related or unrelated donor, since CB HCT is associated with a lower risk of chronic GVHD.

Unrelated double CB HCT for adults with leukemia and hematologic malignancies

Results with double CB HCT support the safety of the procedure [76,77]. In double-unit CB HCT, only one of the two CB units wins out early on in the vast majority of reported cases. Reasons for this are still unknown Towards a better understanding of this phenomenon, an in vivo mouse model double-unit human CB engraftment was developed that correlated with clinical engraftment of the same CB units as used in the mouse model [78]. It was suggested that unit dominance was an in vivo effect perhaps associated with a graft-versus-graft immune interaction mediated by $CD34^-$ cells. Figure 39.3(a) and 39.3(b) shows survival curves of 354 and 282 adult patients with acute leukemia transplants with double CB HCT, respectively, in the RIC and MAC settings. In 2007, in this context, 110 patients with hematologic diseases were evaluated in the setting of a RIC regimen [79]. Neutrophil recovery was achieved in 92% of the cases. TRM was 26% at 3 years. Survival and DFS at 3 years were respectively 45% and 38%. More recently, the Société Française de Greffe de Moelle et de Thérapie Cellulaire in collaboration with Eurocord analyzed 155 consecutive CB HCTs performed using a RIC regimen (V. Rocha for Eurocord, unpublished data). The CI of neutrophil engraftment at day +60 was 80%; autologous recovery was seen in 14% of patients. In multivariate analysis, factors independently associated with better neutrophil recovery were $CD34^+$ cell dose ($>1.2 \times 10^5$/kg) ($p = 0.04$), HLA compatibility (0–1 vs. 2–3) ($p = 0.05$), and previous autograft ($p < 0.01$). The CI of TRM was 18% at 18 months. The estimated probability of OS and DFS at 18 months was 62% and 51%, respectively. A regimen of low-dose TBI, fludarabine, and cyclophosphamide used as RIC was associated with better outcomes than other RIC regimens. More recently, the Minnesota group in collaboration with CIBMTR has confirmed this observation [80].

Outcomes after double, compared with single, CB HCT in adults with acute leukemia

In a single center analysis of 177 patients with acute leukemia, relapse was significantly lower for early stage (1st and 2nd CR) patients who received double CB units compared to single-unit CB HCT, suggesting a possibly greater GVL effect. DFS was 40% and 51% for single and double CBT recipients, respectively [81]. The Eurocord group has published comparable results of single and double UCBT for patients with lymphoid malignancies [75]. In preliminary analysis, Eurocord with the Acute Leukemia Working Party of EBMT have compared outcomes after double with single CB HCT (in the single CB setting, patients receiving $>2.5 \times 10^7$/kg) in adult patients with AML and ALL in remission in two different analyses according to type of conditioning regimen. Double CB HCT was associated with decreased relapse incidence and improved LFS only in patients transplanted in 1st CR after RIC (V. Rocha for Eurocord, unpublished data), results needing confirmation.

Outcomes after double CB HCT compared with HLA-matched sibling and HLA-matched and -mismatched unrelated HCT after myeloablative conditioning

Analysis of 536 patients with malignant disease (AML, $n = 211$; ALL, $n = 236$; CML, $n = 70$; and MDS, $n = 19$) transplanted with an HLA 8/8 allele-matched related (MRD, $n = 204$) or unrelated donor

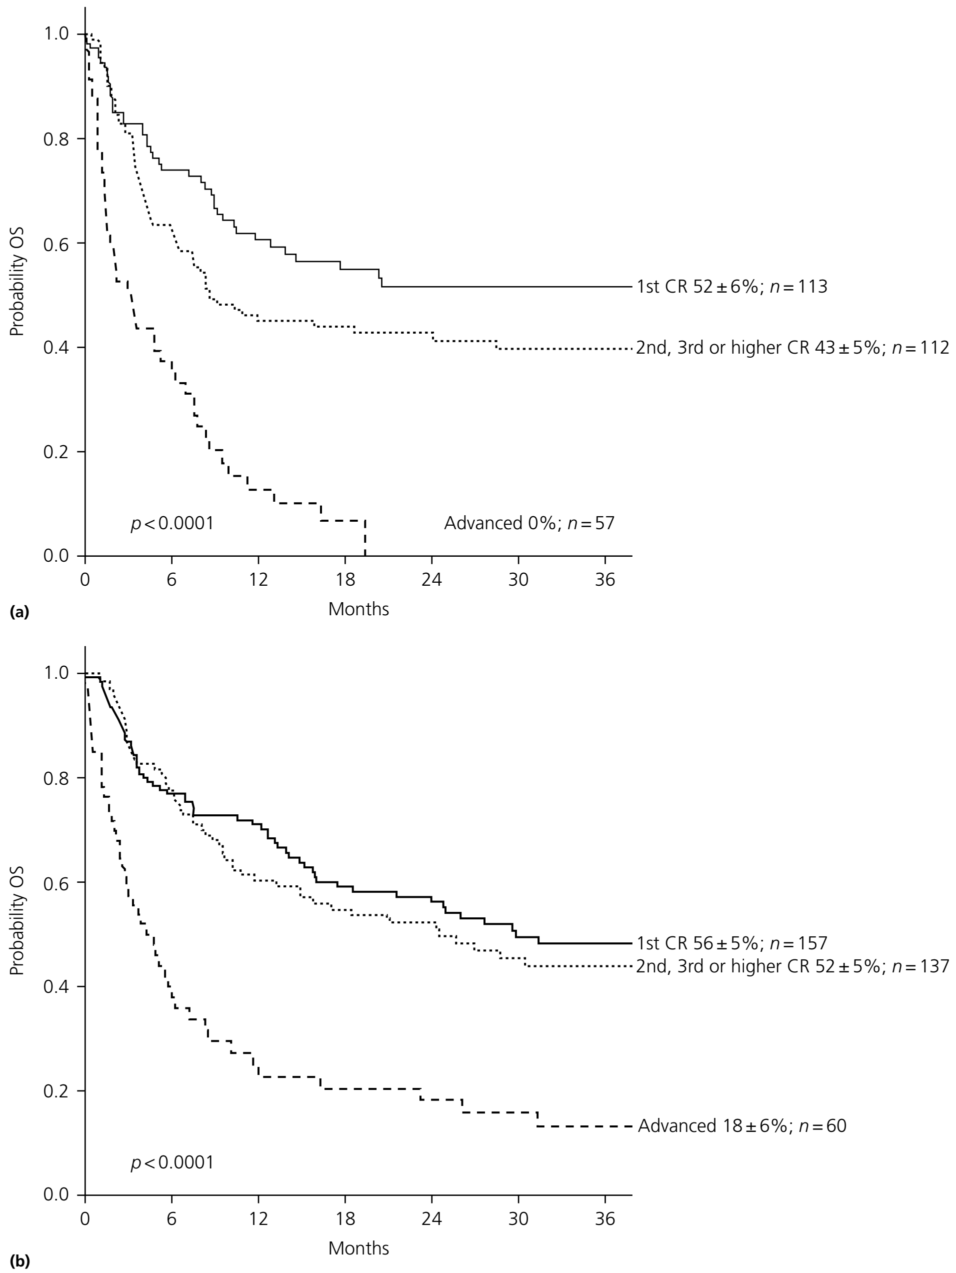

Figure 39.3 Two-year survival for adults with acute leukemia given (a) an unrelated double CB HCT using reduced-intensity conditioning based on disease status and remission; (b) unrelated double CB HCT using myeloablative conditioning based on disease status and remission.

(MUD, n = 152), 1 allele-mismatched unrelated donors (MMUD, n = 52), or double UCB (n = 128) has been published [82]. All patients received MAC with cyclophosphamide and TBI, with fludarabine administered prior to double CB HCT and recipients receiving GVHD immunosuppression with a calcineurin inhibitor and either methotrexate (MRD, MUD, and MMUD) or MMF (MRD and double CB). Median follow-up of survivors was 3.1 years. Double CB HCT was associated with slower hematopoietic recovery compared to other HSC sources. Despite greater HLA mismatch, the CI of grade II–IV acute GVHD and chronic GVHD were lowest after double CB HCT, but risk of relapse was remarkably low while TRM was elevated, resulting in similar DFS. Thus, in the absence of a MRD donor, using either MUD or double CB HCT yields encouraging DFS results.

Outcomes after double CB HCT compared with unrelated MPB HCT in adults with acute leukemia after RIC regimen

Efficacy of double CB HCT was compared with PBCS from 8 of 8 or 7 of 8 HLA-matched unrelated donors receiving RIC regimens [83]. Compared with matched 8/8 PBSC, TRM and overall mortality were similar after double CB (low-dose TBI, fludarabine, cyclophosphamide = TCF) (p = 0.72; p = 0.60), but higher after double CB-other RIC (p = 0.0001; p = 0.004). Compared with 7/8 PBSC, TRM (but not overall mortality) was lower after double CB-TCF-HCT (p = 0.04; p = 0.41). Probabilities of survival after double CB-TCF-HCT, double CB HCT-other RIC, and 8/8 MPB and 7/8 PBSC were 38%, 19%, 44%, and 37%, respectively. With similar survival after 8/8, 7/8 matched PBSC, and double CB-TCF, results support use of double CB-TCF-HCT in adults with acute leukemia who may benefit from RIC transplantation urgently, or who lack a 7/8 or 8/8 unrelated donor.

Recent reviews on CB HCT are available for: leukemia in children [84], treatment of non-malignant disorders [85], extending use in adults [86], double CB HCT for malignant disorders [87], engraftment after double unit CB HCT [88], RIC and double CB HCT [89], and why CB may be underutilized [90].

Selection of CB units

Table 39.4 lists the steps that can help search coordinators and clinicians choose a CB unit based on a patient's disease and donor-related factors.

The combined impact of prefreeze TNC dose and HLA match upon CB HCT outcome was analyzed in recipients of 6/6 matched to 3/6 HLA-A, -B antigen, and -DRB1 allele-mismatched CB units [91]. The study demonstrated that the best outcome for neutrophil and platelet engraftment, acute GVHD, TRM, treatment failure, and overall mortality was associated with the transplantation of 6/6 HLA-matched units, regardless of the TNC dose. The next best survival outcomes were observed in recipients of 5/6 HLA matches with a TNC dose of 2.5 × 10^7/kg or greater, or 4/6 HLA-matched units with a TNC dose of 5.0 × 10^7/kg or greater. However, other factors such as diagnosis (hemoglobinopathies or bone marrow failure syndromes) have an important role in rate of engraftment, due to the fact that most patients with hemoglobinopathies have a full marrow and have not received chemotherapy or immunosuppression before conditioning, or, in the cases of aplastic anemia, they have often received previous multiple transfusions or had a severe infection at the time of transplantation, thus increasing the risk of non-engraftment and mortality. Recently, given that requirements regarding cell dose and HLA matching may differ in malignant and non-malignant diseases, an algorithm was constructed to guide clinicians in choosing the "best" cord blood unit, taking into account the impact of diagnosis, cell dose, and HLA incompatibilities, in patients receiving a single CB HCT. If the TNC dose with a single unit is not available, a double CB HCT should be investigated. In the malignant disease group, Eurocord and others have found that cell dose was the most important factor influencing outcome, increased the risk of delayed engraftment, and led to a higher incidence of TRM and chronic GVHD; however, the number of HLA disparities decreased the risk of relapse, resulting overall in a

Table 39.4 Recommendations for unrelated cord blood unit selection and transplantation

To start, choose a CB unit, consider the diagnosis and also the *presence of a patient's HLA antibodies against the HLA of the CB unit*. HLA compatibility is more important for patients with non-malignant disorders than for malignant disorders.

If the below criteria on cell dose for a single CB HCT is not achieved, a double CB HCT should be proposed, or patients be included in other prospective trials.

Recommendations for HLA and cell dose

HLA (defined based on HLA antigens for -A and -B and allelic typing for HLA-DRB1)

- **CB unit with 6/6 or 5/6 HLA match.** Prefer HLA-A or HLA-B than DRB1 mismatches. Probably, HLA-DRB1 mismatch can lead to high GVL effect in patients transplanted in non-remission (based on Eurocord unpublished and preliminary data). If CB unit 4/6, avoid mismatches in HLA-DRB1 and avoid using this unit for transplantation in patients with non-malignant disorders; use those mainly for bone marrow failure states.
- It is not recommended to transplant CB units with 3/6 or 4/6 HLA disparities.
- **HLA-C** (antigenic typing, 2 digit level) should be performed when there are many CB units available: 6/6 or 5/6 or for those units 4/6 with HLA-DRB1 mismatches [126]. The association of HLA-C mismatches with HLA-DRB1 is associated with higher mortality.
- **HLA and double CB HCT.** There is insufficient data on the role of HLA in double CB HCT.

TNC and CD34$^+$cell dose

Malignant disorders:

Nucleated cell dose: **at freezing, minimum cell dose 2.5 to 3.0 × 10^7/kg, or after thawing, minimum dose of 2.0 to 2.5 × 10^7/kg***

(This recommendation is based on Eurocord, New York Placental Blood Center, and CIBMTR data.)

* If the nucleated cell dose infused is inferior to 1.0 × 10^7/kg, an immediate second transplant should be discussed since early mortality associated with this TNC dose is around 70%.

* If the TNC dose infused is between 1.0 to 2.0 × 10^7/kg, it is recommended to take into consideration the number of CD34$^+$ cells and CFU-GM in order to try to predict the probability of neutrophil recovery and to discuss the possibility of a second transplant. If both cell doses are lower than recommended, a BM aspirate and chimerism analysis should be performed between day +20 and day +28 to confirm the absence of engraftment that indicates a need for a second transplant.

For **double CB unit**: the minimum cell dose of one unit should be higher than 1.5 × 10^7/kg at freezing. Although there is no data to support this recommendation, it was based on the first studies of double CB HCT [79]. Eurocord data was unable to find any association between the sum of TNC dose of both units and the outcomes.

CD34$^+$ cell dose: **at freezing, 1.0 to 1.7 × 10^5/kg, or after thawing, around 1.0 to 1.2 × 10^5/kg**

This recommendation is based on published data [61,63,66]. Due to variation in techniques of counting CD34$^+$ cells, this recommendation should be received with caution. **For double CB HCT**, Eurocord and Société Française de Greffe de Moelle et de Thérapie Cellulaire data have shown an association between the sum of CD34$^+$ cell dose of both units and neutrophil recovery and transplantation-related mortality of more than 1.2 × 10^5/kg pre-freeze CD34$^+$ cells.

Colony-forming unit assay: when available, the CB bank should provide this information with that of the methodology used to set up the assay (semi-solid medium, cytokines, O_2 tension) and score the colonies. This assay is important to evaluate the functional capacity of HPCs after thawing an aliquot or after thawing the product; however, it is difficult to establish a generalized CFU-GM dose due to variations of colony setup and counting between centers.

Non-malignant disorders:

Nucleated cell dose: **at freezing, minimum cell dose 3.5 × 10^7/kg, or after thawing, minimum 3.0 × 10^7/kg**

For patients with BM failure syndromes (aplastic anemia or congenital bone marrow failure states) or hemoglobinopathies, the number of TNC at freezing should be greater than 5 × 107/kg [89,104].

CD34$^+$ cell dose: **at freezing or after thawing, >1.7 × 10^5/kg**

(There is not enough data for this recommendation. This cut-off is based on the greater cell dose for a malignant disorder.)

Colony-forming unit assay: See above section on malignant disorders.

Other considerations:

If there are many CB unit choices available following the above criteria, take into consideration the following:

1. **Allele HLA typing of HLA-A, -B, -C**: A still preliminary analysis by Eurocord and CIBMTR indicates that CB units with 3/8, 4/8 and 5/8 matches should be performed only using a CB unit with a TNC dose >5 × 10^7/kg.
2. **NIMA**: Two retrospective registry-based analyses have demonstrated the favorable impact of NIMA matching on outcomes after CB HCT [162]. The frequency of NIMA matching for CB units in those studies was below 10%. CB banks are currently capturing the HLA type of the mother of the donor CB unit with the aim of prospectively selecting a CB unit based on NIMA.
3. **KIR ligand**: There is conflicting data on the role of KIR on outcomes. If there are many choices of CB units, KIR ligand should be determined for patients with AML [154,155].
4. **ABO compatibility**: In spite of limited evidence, ABO should be taken into consideration when there is a choice between many CB units.
5. **Accredited cord blood bank**: For safety only accredited banks recognized by national and international organizations should be used.

lack of influence of HLA mismatching on OS and DFS, except for those given three or more disparities out of six. Type of HLA mismatch did not influence outcome, but matching for HLA-DRB1 appeared better for patients receiving a graft that had two HLA incompatibilities. Increasing cell dose abrogated effects of HLA mismatching, but not for grafts with three or four HLA incompatibilities. Thus, patients with non-malignant disease should receive a higher cell dose to obtain engraftment than patients with a malignant disease. In non-malignant disorders, HLA mismatching played a major role in engraftment, GVHD, TRM and survival, which was partially abrogated by increasing cell dose.

Other considerations when selecting a cord blood unit

Although availability of adequate cell dose and HLA-matched CB units is important, a number of other factors need to be considered when selecting one or two CB units for transplantation. The first consideration is related to the best CB cell content marker before freezing or after thawing. Most of the studies have analyzed the impact of TNC dose at freezing or after thawing. Among nucleated cell subpopulations, numbers of erythroblasts should be considered [92]. CD34$^+$ cells are probably a better cell marker than TNC since they may better reflect the HSC and HPC content; however, numbers of TNC or CD34$^+$ cells do not necessarily reflect functional HSC content. Due to logistic, technical, and economic conditions, use of HSC or HPC functional cell assessment is difficult to perform routinely in all collection centers as a surrogate marker for CB unit choice.

Studies in BM HCT have identified the importance of allelic disparity of HLA class I (-A, -B, and -C) and class II (mainly DRB1) in determining transplant outcomes. Although HLA matching at an antigen level (low or intermediate resolution) for HLA-A and -B, and allele level matching for HLA-DRB1, continues to be the current standard for CB unit selection, retrospective analyses have evaluated the impact of undetected allelic disparities in a subset of CB recipients. Data from 122 donor-recipient pairs showed important changes in HLA-A, -B, and -DRB1 matching status between the initial assignments (antigen level for HLA-A and -B) and allele level for HLA-A and -B [93]. Over half (9 out of 16) were previously matched at 6/6 at an allele level. However, when additional HLA loci such as HLA-C and HLA-DQB1 were determined, only 14% of the patients were matched for 9–10/10 alleles, 63% were matched for 6–8/10, and the remaining 23% were more extensively mismatched. It was not possible to associate allele typing and outcomes, since numbers of patients were small in the different categories of mismatches, and this was a heterogeneous group of patients. The COBLT study [42] reported 179 patient–donor pairs using high-resolution typing for HLA-A and HLA-B. Matching at high-resolution typing was associated with decreased incidence of acute GVHD, but not with time to neutrophil or platelet engraftment. To determine the real value of allele typing in CB HCT, hundreds of patient–donor pairs will be needed. CB banks and transplant centers are encouraged to perform this typing or to freeze DNA samples in order to retrospectively evaluate the impact of HLA allele typing on CB HCT outcomes.

Eurocord in collaboration with CIBMTR analyzed the impact of matching for HLA-C [94] in CB HCT, knowing that the current selection of CB units is based on antigen-level HLA typing at HLA-A and -B and allele level at DRB1. Eight hundred and three patients/CB donors were studied with HLA-C data at an antigen level. These data suggest that the present strategy for CB selection should be reassessed. Matching at HLA-C for units that are matched at HLA-A, -B, or -DRB1 or in the presence of a single locus mismatch at HLA-A, -B, or -DRB1 should be included to minimize mortality risks.

Donor KIR-ligand incompatibility in the GVHD direction is associated with decreased RI and improved LFS after haploidentical and HLA-mismatched unrelated HCT. Outcomes of 218 patients with AML ($n = 94$) or ALL ($n = 124$) in CR were assessed who had received a single unit unrelated CB HCT from a KIR-ligand compatible or incompatible donor [95]. KIR-ligand incompatible CB HCT showed decreased RI ($p = 0.05$), improved LFS ($p = 0.0016$), and overall survival ($p = 0.004$). Results were more evident for AML transplant recipients, in whom 2-year RI and LFS with or without KIR-ligand incompatibility were 5% versus 36% ($p = 0.005$), and 73% versus 38% ($p = 0.012$), respectively. The Minnesota group examined clinical impact of KIR-ligand mismatch in a heterogeneous cohort of 257 patients with all malignant disorders, transplanted in remission or advanced phases of the disease, given RIC ($n = 102$) or MAC ($n = 155$) and single ($n = 91$) or double ($n = 166$) unit CB grafts [96]. Following RIC, KIR-L mismatch between the engrafted unit and the recipient resulted in significantly higher rates of grade III–IV acute GVHD and TRM with inferior survival [95]. Therefore, more studies are needed to analyze the impact of KIR-ligand matching.

Donor-specific anti-HLA antibodies have an impact on neutrophil and platelet engraftment after CB HCT. Since most CB HCTs are HLA mismatched, presence of anti-HLA antibodies in the patient, donor-specific against the HLA of the CB should be tested. In a Japanese study [97], 648 recipients of a single CB unit and myeloablative CB HCT were analyzed retrospectively. The results suggested that patients' pre-transplantation anti-HLA antibodies should be examined and considered in the selection of CB units.

In the double CB HCT setting, two studies with differing results are available on the impact of anti-HLA antibodies and outcomes. One reported 73 patients receiving double CB HCT showing an increased risk of graft failure and lower survival for patients with positive anti-HLA antibodies [98]. Another showed no association between presence of anti-HLA antibodies and transplant outcomes in 126 double CB HCT recipients [99]. Donor-specific anti-HLA-antibodies (DSA) in recipients of unrelated CB HCT appear to be associated with graft failure and higher mortality, and screening patients for DSA before unrelated CB HCT is recommended before choosing an HLA-mismatched CB unit [100].

Non-inherited maternal antigens (NIMA) promote tolerance in solid organ transplant recipients implying that fetal exposure to NIMA may promote lasting tolerance in humans. NIMA-matched single CB HCT was associated with higher neutrophil recovery and lower mortality rates [101]. A Eurocord–CIBMTR study [102] showed a lower TRM and better survival after CB HCT when selecting a NIMA-matched CB unit; however, the frequency of NIMA matching was below 10%. Cord blood banks are currently capturing information on the HLA of the cord blood unit's mother with the aim to prospectively select a CB unit based on NIMA. Recently, indirect evidence has suggested that perhaps microchimerism from maternal donor cells may mediate a GVL effect in CB HCT [103]. Whether or not this observation is of value in selecting a CB unit has to be further investigated.

ABO major incompatibility has been associated with decreased survival and disease-free survival rates in CB HCT for children and adults with hematologic malignancies [42,104]. However, in many analyses, ABO compatibility is not as robust a factor as cell dose and

HLA. When many CB units are available, choice of the CB unit that is ABO compatible or with minor incompatibilities should be taken into consideration.

A relationship between race and ethnicity and survival of recipients after single CB HCT has been reported for both adults and children with leukemia and MDS [105]. Black recipients had inferior survival to Caucasians but the outcomes were improved when single CB units with a higher TNC dose were used.

In addition to Table 39.4, other reports on selection of an optimally engrafting CB unit have been published [106,107]. Moreover, efforts have gone into predicting the quality of transplantable CB collection through a multiparameter Apgar scored system [108,109].

Improving outcomes after CB HCT

Factors related to procedures of HCT, such as conditioning regimen and GVHD prophylaxis may be associated with time to engraftment. In a Eurocord study, the use of fludarabine in MAC was associated with improved neutrophil and platelet recovery in adult CB HCT (V. Rocha for Eurocord, unpublished data). In Fanconi anemia patients, use of fludarabine in the preparative regimen has been associated with improved engraftment independent of cell dose and HLA in CB HCT [47]. Conversely, use of MTX-containing regimens for GVHD prophylaxis has been associated with delayed engraftment and increased risk of graft failure in patients with hemoglobinopathies and malignant diseases transplanted with an HLA-identical sibling CB unit. In Europe and the United States, the most common regimen is calcineurin inhibitor-based GVHD prophylaxis alone or in combination with corticosteroids or MMF. New protocols for GVHD prophylaxis, using sirolimus-based reagents are reported in the RIC and double CB HCT setting [110]. Prospective studies are needed to establish the best GVHD prophylaxis in the setting of CB HCT.

Immune reconstitution after CB HCT

Immune cell recovery after HCT is a complex process [111]. Effects of delayed immune reconstitution after CB transplantation is most obviously manifest by increased incidence in opportunistic infections [112]. A high incidence of serious infections and infection-related mortality is apparent in the first 3–6 months following CB HCT [113–115], due, in large part, to phagocytic cell- and T-cell-mediated immune deficits before the onset of thymopoiesis which becomes appreciable 6 months or so after HCT [116].

The kinetics of lymphocyte subset recovery after CB HCT has been well described [117–121], and are summarized in Figure 39.4. Natural killer (NK) cells are detectable in peripheral blood at 1 month after transplantation in almost all patients, and reach age-appropriate normal levels at a median time of 2–3 months [118,120]. Early recovering NK cells are predominantly CD56$^{\text{bright}}$ and preferentially express the inhibitory receptor NKG2A, but have a high potential for cytokine production, including interferon (IFN)-γ [122–124]. NK cell recovery remains rapid after CB HCT because CB is a rich source of HPC with the capacity to develop into NK cells upon influence of instructive cytokines [125,126], including a novel myeloid-like NK cell progenitor [127,128].

B cells also rapidly recover reaching normal numbers at a median time of 6 months after transplantation, with IgG, IgM, and IgA levels remaining normal in the post-transplant period in the vast majority of patients [118]. This recovery is associated with a well-diversified B-cell repertoire by day +90 as assessed by B-cell receptor V_H complementarity determining region 3 (CDR3) [129]. A high proportion of the B cells recovering in the first 6 months after CB transplantation have the phenotype of regulatory B cells ($IgM^+IgD^+CD38^+CD5^+$ B cells), the number of which exceeds that found in normal donor peripheral blood [129].

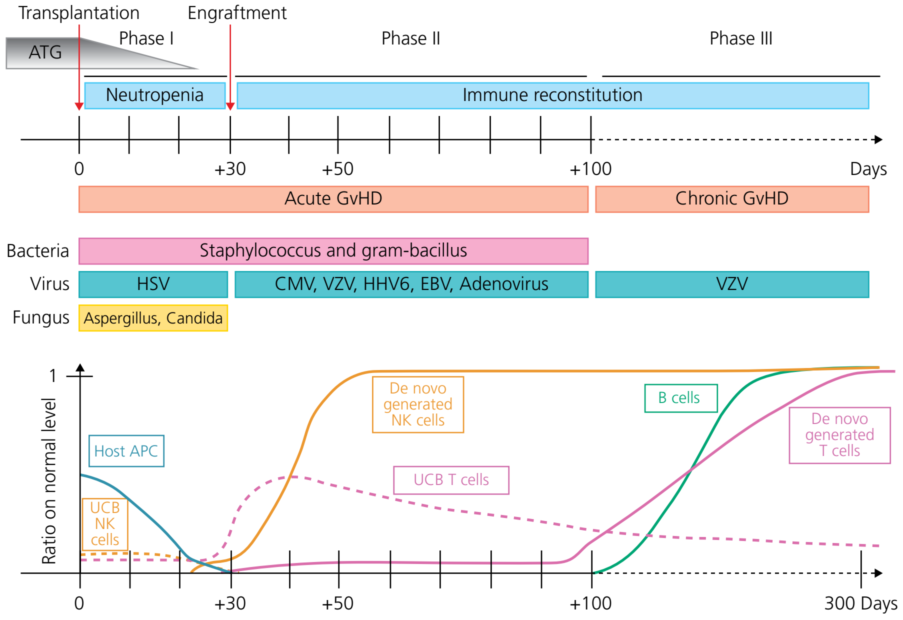

Figure 39.4 Kinetics of immune reconstitution and transplant-related complications following UC HCT. The pre-engraftment period (Phase I, Days 0–30) is characterized by general immunosuppression, including neutropenia, with high susceptibility to bacterial and fungal infections. Host residual antigen-presenting cells (APC) progressively disappear during this phase. In the post-engraftment period (Phase II, Days 31–100), NK cells reach normal levels by about 1 month after transplantation, and may represent 80% or more of the recipients peripheral blood lymphocyte count. UCB-derived T cells also persist during this phase and undergo antigen-driven thymic independent expansion. During this phase, there is susceptibility to bacterial as well as viral infections. In phase III (beyond Day 100), there is progressive B-cell reconstitution and de novo generation of T cells through thymopoiesis. Recovery of thymopoiesis is usually significantly more prolonged in adults. Source: Merindol et al. 2011 [121]. Reproduced with permission of Wiley & Sons.

T cells are slowest to recover after CB HCT. $CD4^+$ T cells recover to normal numbers after a median of 12 months, but $CD8^+$ T cells recover somewhat faster, reaching normal numbers after medians of 8–9 months [118,120]. Recovered T cells appear to show normal responses to common mitogens, including phytohemagglutinin, concanavalin A, and pokeweed mitogen, by 6–9 months after transplantation [118]. Unlike PBSC or BM grafts, T cells contained in CB are predominantly naïve ($CD45RA^+CD62L^+CD27^+CCR7^+$) recent thymic emigrants [130]. Therefore, the overwhelming majority of T cells that emerge during the first 3–6 months after CB HCT are peripherally expanding graft-derived T lymphocytes. While naïve T cells present in CB grafts give rise to antigen-specific T-cell-mediated immunity, protection against infection may not be entirely effective [131], possibly because this pathway of expansion leads only to a skewed T-cell repertoire with limited responses against newly encountered antigens. By 3–6 months after CB HCT, thymus-derived T-cell reconstitution becomes detectable, as assessed by TREC-containing T cells, reaching normal range at approximately 9–12 months post-transplantation in pediatric patients [132,133].

There is currently no evidence that kinetics of immune cell subset reconstitution are substantially different following double versus single CB HCT [58,134,135], with the possible exception of enhancing the development of TREC-containing cells following CB HCT in adult patients [136]. In the largest reported study to date, investigators recently compared lymphocyte subset reconstitution in children undergoing transplantation using CB ($n = 112$) with those undergoing unmanipulated unrelated BM HCT using a competing risk analysis [137].

A higher nucleated cell dose collected in the CB unit has been associated with faster total T cell and $CD8^+$ T-cell recovery [120]. Greater HLA mismatch and development of acute GVHD have been significantly associated with slower T-cell recovery, with the effect of acute GVHD impairing $CD4^+$ T cells [120]. While the intensity of the preparative regimen has not been shown to affect immune cell subset recovery or immunoglobulin reconstitution [138], TBI and anti-thymocyte globulin (ATG) administration have been reported to delay T-cell recovery [139].

Clinical immune outcomes following UCB transplantation

Few studies have attempted to correlate immune cell recovery with risk of opportunistic infections [118,140]. In the largest study including pediatric CB recipients from Duke University [140], a higher $CD3^+$ cell dose in the CB graft (together with a higher $CD34^+$ cell dose, negative recipient CMV serology, greater HLA match, and younger age) was found to predict a lower risk of death from opportunistic (mostly viral) infections at 6 months after transplantation, suggesting that in vivo expansion of infused post-thymic T cells contained in the CB graft could provide protection from infection. Additionally, CB recipients who developed opportunistic infections by day +100 have a significantly reduced probability of overall survival compared to those who did not have infection. Also, patients who developed opportunistic infections showed greater evidence of in vivo expansion of infused naïve T cells contained in the graft together with the emergence of T-cell subsets with a Th1/Tc1 cytotoxic phenotype as early as 2–3 weeks after HCT.

Immune cell recovery may impact risk of relapse and survival after CB HCT. Rapid lymphocyte recovery after CB HCT is associated with improved clinical outcome. In multivariable analysis, an absolute lymphocyte count (ALC) of $>0.2 \times 10^9$/L at day +30 ($n = 73$) after myeloablative conditioning was associated with superior 2-year overall survival (73% vs. 61%; $p = 0.02$), progression-free survival (68% vs. 54%; $p = 0.05$), and less transplant-related mortality (8% vs. 28%; $p < 0.01$) compared to patients whose ALC was $<0.2 \times 10^9$/L ($n = 43$). Similarly, for patients receiving reduced-intensity conditioning, an ALC $>0.2 \times 10^9$/L at day +42 ($n = 105$) was associated with superior 2-year overall survival (59% vs. 41%; $p < 0.01$) and progression-free survival (46% vs. 36%; $p = 0.05$). Notably, there was no significant relationship between ALC and relapse [141].

Although ALC and other immune cell numbers have not been predictive of relapse, antigen-specific immune reconstitution has been associated with reduced leukemia relapse and improved relapse-free survival following CB transplantation [142,143]. A robust T-cell response to at least one herpes virus was a strong predictor of relapse-free survival. Conversely, a high level of expansion of $CD8^+$ T cells co-expressing programmed death-1(PD-1), an inhibitory receptor of the CD28 family highly expressed on dysfunctional T cells during chronic viral infections [144], early following CB HCT has been associated with leukemic relapse [131], suggesting that excessive numbers of $PD\text{-}1^+CD8^+$ T cells may be a surrogate marker of defective immune reconstitution. The importance of reconstitution of thymopoiesis has been underscored by the observation that while $CD8^+$ T cells capable of secreting IFN-γ in a CMV-specific enzyme-linked immunosorbent spot (ELISpot) assay can be detected as early as 8 weeks after UCB transplantation, these cells are not capable of clearing CMV viremia [136]. Clearance of CMV viremia occurred later with recovery of $CD4^+CD45RA^+$ T cells, and was dependent on reconstitution of thymopoiesis and attainment of TREC levels of 2000 or more copies/μg DNA.

Future directions for enhancing CB HCT

Potential means to increase numbers of collected CB cells and/or ex vivo expand CB HSC and HPC

Means to enhance CB HCT have been reviewed [145]. A simple means to get more cells from a CB collection is to collect more cells at the birth of the baby. While perfusion techniques have been used for this purpose after the placenta is removed from mother [146], this ex vivo procedure is technically challenging, and is not likely to be available except at select collection sites. Another means is to collect and process cells under hypoxic conditions (e.g. 3% O_2) or in ambient air in the presence of cyclosporine A which prevents mitochondrial permeability transition pore opening, increased release of mitochondrial ROS, and enhances by 2-5 fold the numbers of transplantable HSC obtained [147,148]. Investigators have also focused efforts on ex vivo expanding of the HSC and HPC in CB already collected. Attempts at ex vivo expansion have met with limited success, but new studies may be promising. A potent combination of cytokines for ex vivo culture of human $CD34^+$ cells for expansion of HPC and repopulating cells in vivo in immune-deficient mice is stem cell factor (SCF), Flt3 ligand (FL), and thrombopoietin (TPO) with other cytokines, molecules, and/or other populations sometimes added to this cocktail of growth factors. Examples of other molecules tested with or without SCF, FL, and TPO include rapamycin [149], SR1 [150], other small molecules [151,152], Notch ligand Delta1 [153], the combination of Delta1 plus HoxB4 [154], as well as other factors, including selected members of the angiopoietin-like family of molecules [155] and chromatin remodeling agents [156,157]. Some have shown some efficacy for ex vivo expansion of phenotypic or functional CB HSC. Notch-mediated expansion of short-term repopulating HSC/HPC populations was demonstrated in a clinical setting [153], as was mesenchymal stromal cells to enhance cytokine-mediated expansion of CB cells [158]. Both clinical studies [153,158] were done in the context of a double CB HCT where ex vivo cultured cells were infused with an unmanipulated CB unit. Both approaches resulted in an apparent shorter time to neutrophil and platelet engraftment. However, it was the unmanipulated CB unit that engrafted long term, and it is not clear if any studies have resulted in ex vivo expansion of long-term repopulating HSC needed for use of such procedures in a single CB HCT setting.

Enhanced understanding of the cells within the microenvironment niche in BM that nurtures survival and other functions of HSC and HPC could also be of use for HSC expansion effort. This niche includes endothelial cells, osteoblasts, and mesenchymal stem/stromal cells (MSC). In mouse models it was demonstrated that parathyroid hormone or a related protein activated and stimulated osteoblasts, which in turn influenced numbers and function of mouse HSC [159]. This led to assessment of parathyroid hormone effects in a phase II trial of double CB HCT [160]. The results were not encouraging, with no enhancing effect on time to neutrophil or platelet engraftment. Mixtures of either endothelial cells, MSC, or other cells with CB cells have been assessed for enhancing the repopulation of CB HSCs in animal models [161,162], but it remains to be determined if such efforts are efficacious for enhancing human CB engraftment of humans. A better appreciation of the intracellular molecules that regulate HSC self-renewal and proliferation should help to increase HSC numbers or activity ex vivo. A large number of such intracellular mediators have been defined [5], but we need to appreciate how these signaling molecules interact with each other to modulate HSC function.

Efforts to enhance the homing and subsequent nurturing effect of the microenvironment on CB HSC

Clinical efforts have been made to bypass the circulation by direct intra-bone marrow injection of CB cells [163]. It is not clear whether this has overcome the problem of delayed time to neutrophil, platelet, or immune cell recovery. HSCs inefficiently home to the BM after intravenous (IV) infusion. Efforts to enhance the homing of HSC to their nurturing BM microenvironmental niche include pretreating donor cells prior to IV injection with either small molecule inhibitors of the enzyme dipeptidylpeptidase (DPP)4 [164–166], agents that enhance fucosylation [167], or prostaglandin (PG)E 1 or 2 [168–170]. In vivo treatment to inhibit DPP4 with small molecules has also enhanced engraftment [166]. Appropriate timing with combination of the above-mentioned targeting reagents may synergize to enhance engraftment. Efforts are ongoing to test the clinical feasibility of PGE, DPP4 inhibition, and fucosylation for enhancement of time to engraftment. An example of potentially improving upon first clinical efforts is that of a pilot clinical study of in vivo DPP4 inhibition to enhance engraftment of single-unit CB HCT in adults with high-risk hematologic malignancies [171], that utilized an FDA approved, orally active DPP4 inhibitor, sitagliptin, (used clinically to treat type II diabetes mellitus). Systemic DPP4 inhibition was well tolerated, and results were encouraging, but not definitive in significantly enhancing time to neutrophil engraftment. It is possible that more frequent administration of DPP4 and for longer periods of time than administered in the pilot study [171], might significantly enhance the time to engraftment with single CB HCT. In fact, using combinations of treatments such as ex vivo short-term culture of CB with either PGE or a DPP4 inhibitor and infusion of these treated cells in patients treated with a DPP4 inhibitor may be more efficacious than each one of these procedures alone [172].

Possibilities for regenerative medicine with cells present in or generated from CB

It is too early to tell if non-hematopoietic cells in CB will be able to be used successfully for therapeutic advantage, in the context of cell replacement or regenerative medicine. CB contains MSCs, which have the capacity, at least in vitro of differentiating down pathways that can produce bone, fat, and cartilage [173–175]. However, there has been variability reported in the literature with regards to the frequency of MSC in different collections of CB [176,177]. Endothelial colony-forming cells (ECFC; perhaps endothelial progenitor cells, EPC) have also been found in CB [178,179], and have been characterized by selected expression of antigenic markers which distinguishes them from blood progenitors [180]. ECFC are present in low frequency in CB, but can be recovered in viable form after thawing CB samples that had been stored in a cryopreserved state for up to 21 years [17]. However, ECFC were present after thawing at 10–20% of numbers found in freshly isolated CB samples. Also, the proliferative capacity of these cells, although still extensive, is not at the levels seen for freshly isolated CB ECFC, suggesting that the freezing procedure that works well for HPC, is not as effective for cryopreservation of ECFC. More efficient cryopreservation techniques may have to be developed for ECFC, and perhaps other non-hematopoietic cells in CB.

Induced pluripotent stem (iPS) cells can be generated from mature cell types, including $CD34^+$ CB cells, through enforced expression of transcription factor such as Oct4, Sox2, KLF4, and c-Myc [181,182] (Figure 39.5). Generated iPS cells have the capacity to produce in vitro, and by teratoma formation assays in vivo in mouse, cells of all three germ cell layers (endoderm, ectoderm, and mesoderm). IPS cells have been generated from $CD34^+$ cells isolated after thawing from unseparated CB cells that had been stored in a cryopreserved state for more than 20 years [17]. Only a low frequency of the iPS cell colonies generated from cryopreserved or fresh CB samples, and from other cells sources used to generate iPS cells, are fully reprogrammed to an ESC-like state [183]. A more fully reprogrammed iPS cell state could be generated in a larger proportion of the cells if in addition to enforced expression of Oct4, Sox2, KLF4, and c-Myc in $CD34^+$, as well as other, cell types, microRNA-302 cluster was also expressed from an exogenously added vector. Epigenetic regulation of Nanog (another important ESC-related transcription factor), by microRNA-302 as mediated through methyl-DNA binding domain protein 2, an epigenetic suppressor, allowed completed iPS cell reprogramming in a larger percentage (~16%) of the cells [183].

While iPS cell generation has the potential to be used to generate all cell types of the body's cells, including blood cells, and we have learned and will continue to learn about cellular processes with iPS cells, whether or not iPS cells, or in fact other non-hematopoietic cells in CB will be a safe and efficient means to be considered for human regenerative medicine remains to be determined [184]. Cells similar to CB endothelial colony forming cells with functional regenerative medicine potential have been differentiated from CB $CD34^+$ derived iPSCs [185]. If in the future, iPS cell technology is found to be of clinical cell replacement use, or other non-hematopoietic cells in CB can be used in a similar manner, this will likely extend the use of cryopreserved CB, which would also enhance the need for more CB banking efforts [184,186]. The future use of CB cells for other than blood cell replacement therapies remains to be proven, and great caution needs to be exercised in this context, including the possible need for enhanced governmental oversight and regulation [187].

CHAPTER 40

Mobilization of Peripheral Blood Hematopoietic Cells for Autologous HCT

Thomas C. Shea[1] **and John F. DiPersio**[2]

[1] Marrow and Stem Cell Transplant Program, UNC Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC, USA

Introduction

High-dose chemotherapy has become an important therapeutic strategy for many malignancies. These regimens are often severely myelosuppressive or myeloablative, and autologous peripheral blood progenitor cells (PBPCs) have been used to provide rapid and sustained hematopoietic recovery to support such treatment. In the past, autologous bone marrow transplantation was used in this setting but, because of the less invasive collection methods and more rapid resolution of neutropenia and thrombocytopenia, PBPC transplantation has largely replaced bone marrow transplantation for the support of high-dose chemotherapy (Figure 40.1) [1,2].

Both hematopoietic stem cells and progenitor cells populate the resting bone marrow. Stem cells are single cells that are clonal precursors capable of giving rise to both identical stem cells (self-renewal) and a defined set of differentiated progenitors. Progenitor cells are multipotent precursor cells that lack the ability to self-renew but, like stem cells, maintain the capacity to differentiate and proliferate. Despite this important difference, these terms often are used interchangeably in the literature [3].

The ability of PBPC to reconstitute hematopoiesis was first described in 1980 and followed by additional reports in 1985 and 1986 [4–6]. Under steady-state conditions, hematopoietic progenitor cells circulate in the peripheral blood compartment at a frequency of approximately 10–100 cells/mL of whole blood. This low frequency of PBPC in the circulation made collecting adequate numbers of these cells a cumbersome process. As a result, methods to mobilize these cells from the marrow compartment and increase their numbers in the peripheral circulation have been developed to foster collection of sufficient cells for clinical use. The work by Abrams [4] and Richman [7] in animal models demonstrating an increase in PBPC following subablative chemotherapy administration in patients following cytokine administration have led to the widespread application of this approach for supporting high-dose therapy [8].

Identification and enumeration

Human hematopoietic stem cells express CD34 and Thy-1 at a high level and c-kit at a low level and do not express lineage specific markers ("Lin") and CD38 [3]. The ability of a mobilized apheresis product to engraft and permanently repopulate the bone marrow depends on its content of both stem cells and progenitor cells. In the transplant setting, this can be evaluated using several assays including colony-forming unit – granulocyte/macrophage (CFU-GM), colony-forming unit – granulocyte/erythrocyte/macrophage/megakaryocyte (CFU-GEMM), and burst-forming unit – erythroid (BFU-E), all of which have been correlated with time to engraftment [8,9]. Because these assays require significant laboratory manipulation, results often reflect technical variability and are difficult to compare.

Quantification of CD34 expressing cells has been used to assess the quality of the apheresis product and its adequacy for repopulating the bone marrow. $CD34^+$ cell content correlates closely with CFU-GM, BFU-E, and CFU-GEMM, as well as time to engraftment of both neutrophils and platelets [10]. $CD34^+$ cell quantification is also subject to intra-laboratory variation, but standardization of procedures can reduce this variation [11,12]. Efforts have also been undertaken to identify subsets of the CD34 cell population that are critical to bone marrow reconstitution, such as $CD34^+CD33^-$, $CD34^+CD33^+$, or $CD34^+CD38^-$ cells [13].

Mechanisms of hematopoietic cell mobilization

Hematopoietic stem cells (HSC) in the bone marrow (BM) exist in a highly organized three-dimensional microenvironment consisting of a diverse group of cell types including stromal cells and an associated extracellular matrix (ECM) rich in fibronectin, collagens, and various proteoglycans. Osteoblasts appear to play a pivotal role in HSC function via a physical interaction that exists between HSC and the BM osteoblasts, thus defining the osteoblastic niche [14]. Other subpopulations of HSCs exist in close proximity with sinusoidal endothelial cells, thus defining the "endothelial or vascular niche" [15]. It is assumed that each of these niches differentially regulate HSC trafficking (homing and mobilization) as well as basic functions such as survival, proliferation, self-renewal, and differentiation. To enter the circulation, HSCs must transmigrate through the vascular barrier (termed the BM–blood barrier) where both endothelial cells and subsequently macrophages are thought to play a role in stem cell migration and release from the marrow microenvironment [16,17]. Several excellent reviews on this topic address the various roles played by these and other factors in this complex process (Figure 40.2) [18–20].

A number of adhesion molecules have been implicated in HSC trafficking. These include stromal cell-derived factor-1

(SDF-1/CXCL12), very late antigen-4 (VLA-4 or a4 integrin), c-kit, CD62 ligand (CD62L), P- and E-selectins, and CD44 [21–23]. In addition to these adhesion molecules, a number of cell-associated chemokines including Gro-beta, Interleukin-8, metalloproteinase-9 (MMP-9 or gelatinase B), and CD26 (dipeptidylpeptidase-4) have been implicated in mediating the release of HSCs from the BM into the PB via cleavage of the candidate adhesion molecule tethers mentioned earlier [24–27].

The kinetics of HSC mobilization can vary dramatically depending upon the mobilizing agents used. Granulocyte colony-stimulating factor (G-CSF) induces maximum HSC mobilization in 4–5 days while granulocyte–macrophage colony factor (GM-CSF) induces maximum stem cell mobilization in 5–6 days. When chemotherapy and G-CSF or GM-CSF are used together, mobilization is optimal after 10–14 days. In contrast, mobilization by chemokines (IL-8 or GRO-β) or chemokine receptor antagonists (plerixafor) result in mobilization of HSC in minutes to hours [18,19,24,28].

Relative to BM HSC, a higher percentage of mobilized PB HSCs mobilized with G-CSF or chemotherapy and G-CSF are in G_0 or G_1 phase of the cell cycle. HSCs are selectively mobilized after M phase of the cell cycle providing a potential explanation for the preponderance of HSC in the G_0 and G_1 phases of the cell cycle in the blood after G-CSF treatment [29]. In addition, consistent with the downregulation of various adhesion molecules contributing to mobilization, circulating HSCs display reduced expression of VLA-4, c-kit, and CXCR4 [29,30].

Evidence for the pivotal role of SDF-1/CXCR4 in HSC mobilization and trafficking

There is convincing evidence that the interaction of SDF-1/CXCL12 with its cognate receptor, CXCR4, generates signals that regulate HSC trafficking in the BM. SDF-1 is a CXC chemokine constitutively expressed in the BM by stromal cells and BM osteoblasts [31]. SDF-1 is a potent chemoattractant agent for HSCs and has been shown to regulate HSC survival, adhesion, and cell cycle status [21]. Analyses of CXCR4-deficient mice have established that both SDF-1 and CXCR4 are necessary for normal migration of HSCs from the fetal liver to the BM and for the efficient retention of these progenitors in the BM [27,28]. Elevation of the SDF-1 levels in the blood by administration of SDF-1 or by the injection of adenoviral vector expressing SDF-1 is associated with significant mobilization of HSCs into the blood. Likewise, injection of a competitive inhibitor of CXCR4 (AMD3100; plerixafor) induces rapid mobilization (9 hours in humans and 3 hours in mice) [28].

Reproduced with permission of Society of Leukocyte Biology and John Wiley & Sons Ltd. (For a color version of this figure, please see the color plate section.)

Interruption of SDF-1/CXCR4 signaling/interaction represents a pivotal and key step in HSC mobilization by G-CSF. SDF-1 levels in the BM decline sharply during G-CSF mobilization [31]. There is evidence to suggest that CXCR4 (expressed on HSCs) and SDF-1 (expressed on BM stromal cells and osteoblasts) may be proteolytically cleaved and inactivated during G-CSF treatment [30] although the role of proteolytic cleavage of SDF-1 by these proteases as the mechanism of G-CSF-induced mobilization has been brought into question by elegant studies in which mice deficient in both NE, MMP-9, and cathepsin G (CG) mobilized HSCs normally in response to G-CSF treatment [32]. Recent data provide compelling evidence that G-CSF induces a dramatic transcriptional downregulation of SDF-1 mRNA in BM stromal cells. The downregulation of SDF-1 mRNA in response to G-CSF occurs in a temporally consistent way with G-CSF-induced mobilization of HSCs (maximum downregulation of SDF-1 and HSC mobilization occurring in 4–5 days) [33]. These data provide prima facia evidence that G-CSF regulates SDF-1 levels and thus HSC mobilization via transcriptional downregulation but they do not eliminate the possibility that G-CSF may also induce mobilization in part by activation of cell-associated proteases. Recent evidence suggests that G-CSF has no direct effect on BM osteoblasts or nestin$^+$ CCL12/SDF-1 abundant reticular cells (CAR) but mediates its suppressive effects on SDF-1 expression in these cells via intermediate cells phenotypically and functionally similar to monocytes. The mechanism by which G-CSF induces downregulation of SDF-1 via these intermediate monocytes remains unclear. Of interest, this same group found that IL-8 in contrast to G-CSF is completely dependent on neutrophils for mobilization [34].

Role of proteases and other cell adhesion molecules on HSC mobilization

Significant data suggest that a highly proteolytic environment is induced in the BM during HSC mobilization by G-CSF [35]. These proteases include NE, CG, and CD26 which appear to increase following G-CSF administration and cleave important adhesion molecules such as VCAM-1, SDF-1, and c-kit [21,22]. The metalloproteinase MMP-9 also appears important in the role of IL-8-induced HSC mobilization [24–26]. The interaction of these proteases in animal models has proven complex, however, leading to the conclusion that at this time, specific proteases or combinations of proteases have not clearly implicated any single or combination of proteases mechanistically in cytokine, chemokine, or chemotherapy-induced HSC mobilization [24,26,27,32,35]. Adhesion molecules that are thought to play a role in stem cell mobilization include VCAM-1, CD44, and P- and E-selectin, both of which are inhibited by fucoidan, the administration of which leads to stem cell mobilization in mice [21,22,35–37]. Recent reports have also helped elucidate the roles of microRNA126, sphingosine-1-phosphate, complement, and constitutional polymorphisms in SDF-1, VCAM-1, and CD44 on the response of individuals to G-CSF administration [38–41]. Several excellent reviews of these processes have recently been published [18,19].

Clinical applications

PBPCs have become the preferred source of autologous stem cells to support the use of high-dose, myeloablative chemotherapy in a variety of diseases [1,2,41–43] and are also being utilized widely in allogeneic transplants [44].

Collection techniques

Once PBPC mobilization is initiated, the timing and volume of apheresis is critical to maximizing yield. For steady-state mobilization with recombinant growth factors (in the absence of chemotherapy), the peak values of mobilized hematopoietic progenitor cells are observed after 4–6 days of treatment in most series [45,46]. Hematopoietic cells are usually collected with an apheresis machine using a technique that is similar to that used for collection of platelets. Small comparison studies have not clearly demonstrated the superiority of one machine over another, but at least one report suggested that use of the COBE Spectra unit resulted in a more rapid collection and higher yield of CD34$^+$ cells in patients undergoing apheresis prior to ASCT for multiple myeloma [47]. Chemotherapy-based mobilization results in an increase in the time required to initiate collection and less predictability as to when this will occur, as maximal mobilization occurs following resolution of the hematologic nadirs produced with chemotherapy-induced myelosuppression. While a number of studies indicate that the combination of chemotherapy and cytokines leads to increased yield of hematopoietic progenitor cells compared to cytokines alone, the variability inherent in blood count recovery following chemotherapy can present a challenge in trying to schedule apheresis procedures. Guidelines and general recommendations for target cell numbers in the peripheral blood have been developed to initiate apheresis and monitoring daily CD34$^+$ cell content in the peripheral blood has become the preferred means by which to predict PBPC yield [48–50]. In one study, a CD34$^+$ cell count of ≥50 cells/μL peripheral blood predicted a CD34$^+$ cell yield of $\geq 2.5 \times 10^6$ CD34$^+$ cells/kg body weight in a single apheresis [51].

In harvesting PBPCs, the goal is to minimize the number of apheresis procedures required to achieve the target hematopoietic progenitor cell dose. To date, the optimal apheresis volume that achieves this goal has not been defined. Large volume apheresis (>15L) has been investigated as a way to decrease the number of aphereses. Initially, there was concern that the large volumes would impair CD34$^+$ cell quantity harvested over collection time. However, in one randomized trial comparing 7-L and 10-L apheresis volumes, the use of a 10-L volume did not decrease the number of apheresis required to collect $\geq 2 \times 10^6$ CD34$^+$ cells/kg [52]. Most reports have demonstrated a correlation between total CD34$^+$ cell yield and the blood volume processed, resulting in varied approaches among institutions including individualized, patient-specific, collection techniques that are frequently based on practical issues such as scheduling and cost [48,52].

Identifying the optimal cell yield

Several groups have identified minimum thresholds ranging from 1×10^6 to 3×10^6 CD34$^+$ cells/kg body weight for sustained engraftment [10,53]. Other investigators have suggested an optimal CD34$^+$ cell dose of ≥ 5–8×10^6 CD34$^+$ cells/kg, with which neutrophil and platelet recovery is accelerated, the demand for other supportive measures (antibiotics, transfusion) is decreased and therapy schedule is more likely to be preserved [50,53]. One report highlighted the fact that although a higher dose of CD34$^+$ cells is unlikely to shorten the median duration of neutropenia or thrombocytopenia in a broad patient population, it will reduce the number of "outlier" patients with prolonged times to engraftment requiring prolonged transfusion support (Figure 40.3) [53]. While some investigators suggest that more primitive CD34$^+$ cell subsets such as CD34$^+$CD33$^-$ or CD34$^+$CD38$^-$ cells are better predictors of durable engraftment,

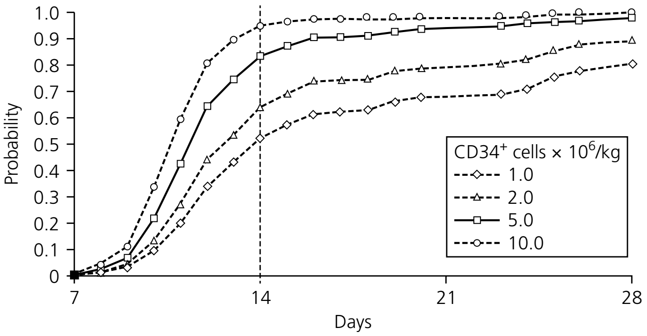

Figure 40.3 This figure demonstrates the achievement of platelet recovery to >50,000/uL post-transplant on the *Y* axis and days post-transplant on the *X* axis as a function of the number of CD34$^+$ cells infused. Note that the median days to platelet recovery does not change but that the frequency of patients with prolonged time to recovery decreases markedly as doses exceed 5 × 10^6 CD34 cells/kg infused. Table 40.1 Comparison of mobilization with granulocyte colony-stimulating factor (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF)

No. of patients	Comparison	Observation	Ref.
29	G-CSF at 6 µg/kg vs. GM-CSF at 8 or 16 µg/kg	G-CSF group: 5.4-fold higher CD34$^+$ cell yield	[45]
44	G-CSF at 5 µg/kg/d vs. GM-CSF at 250 µg/kg/d or 125 µg/kg BID	No difference in G-CSF vs. GM-CSF induced CD34$^+$ cell yield	[54]
156	G-CSF + chemotherapy vs. GM-CSF + chemotherapy	G-CSF group: 3.5-fold increase in CD34$^+$ cell yield	[55]
95	Unprimed vs. 5 or 10 µg/kg G-CSF	3–6-fold more CD34 cells with 5 or 10 µg/kg than for unprimed patients	[46]

BID, twice daily; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor.

Table 40.2 Comparisons of cytokine doses and combinations for mobilization

No. of patients	Comparison	Observation	Ref.
	Cytokine doses		
82	Mobilization with chemotherapy + filgrastim, molgramostim, or lenograstim	No statistically significant difference in CD34 cells collected in any one group over the others	[73]
52	Peg vs. G in autologous patients	6 mg of pegfilgrastim was comparable to 10 µg/kg G-CSF	[74]
45	6 vs. 12 mg pegfilgrastim vs. 8 µg/kg G-CSF + chemo	Comparable CD34 yields with allo doses and an insignificantly lower CD34 yield	[75]
144	No growth factor vs. GM-CSF: 125 µg/m^2/day vs. 250 µg/m^2/day	GM-CSF 125 µg/m^2/day and 250 µg/m^2/day groups: five- and 12-fold increase in PBPCs compared to no growth factor	[57]
75	G-CSF: 10 µg/kg vs. 24 µg/kg G-CSF in normal donors	1.7-fold increase with higher dose G-CSF	[56]
72	G-CSF: 10 µg/kg QD vs. 5 µg/kg BID vs. 8 µg/kg BID in healthy donors	Modest benefit from split dose	[59]
50	G-CSF: 10 µg/kg QD vs. 5 µg/kg BID to healthy volunteers in a crossover design with a washout period in-between	Split dose led to approximately a twofold increase in CD34 cells/donor.	[60]
	Cytokine combinations		
156	Chemo + G-CSF vs. chemo + GM-CSF followed by G-CSF	No difference in CD34$^+$ cell yield (but both regimens yielded 3.5-fold more CD34$^+$ cells than chemo + GM-CSF)	[55]
40	G-CSF or GM-CSF vs. GM-CSF followed by G-CSF	GM-CSF f/b G-CSF group: 2.3-fold increased yield of CD34$^+$ cells.	[68]
302, 298	G-CSF alone was compared to G-CSF + plerixafor in separate studies in patients with multiple myeloma or lymphoma who then underwent apheresis	In each case, CD34 yields were higher with the combination than with G-CSF alone resulting in fewer days of collection to achieve the targeted apheresis yields	[66,67]

BID, twice daily; chemo, chemotherapy; DFS, disease-free survival; f/b, followed by; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; OS, overall survival; PBPCs, peripheral blood progenitor cells; QD, every day.

most centers continue to rely on total CD34$^+$ cell numbers as the most reliable indicator of an adequate PBPC population [10,13,48,50].

Cytokine and cytokine plus chemokine-induced mobilization

G-CSF and GM-CSF have been used alone to increase circulating CD34 cells or CFU-GMs compared to that found in the unmobilized, steady state, and mobilize PBPCs from cancer patients at doses from 3 to 24 µg/kg/day by subcutaneous injection [8,9,45,46]. A number of studies have compared the use of G-CSF and GM-CSF for mobilization both alone and in conjunction with chemotherapy [45,54,55]. While most have found that G-CSF provides a higher yield of PBPCs, both growth factors reliably mobilize cells into the circulation with minimal toxicity (Table 40.1) [45,46,54,55]. A dose–response to G-CSF, with higher doses resulting in increased CD34$^+$ peripheral cells, has been demonstrated. One group compared G-CSF doses of 5 and 10 µg/kg/day [50] while other groups compared G-CSF doses of 10 or 24 µg/kg/day [56]. In these studies, the higher dose resulted in superior collections of CD34$^+$ cells (Table 40.2). Higher doses of GM-CSF have likewise been shown to improve yield of CD34$^+$ cells [57]. Higher doses of G-CSF have also been used successfully to mobilize and collect cells in patients who have failed to collect following lower cytokine doses [58]. Studies in normal donors providing hematopoietic progenitor cells for allogeneic transplant recipients or in autologous patients prior to transplants for lymphoma or myeloma have not found a consistent benefit for once versus twice daily administration [48,59–61] and patient/donor convenience and comfort should probably be the determining factor at this time.

The timing of apheresis initiation following cytokine administration has also has been examined. One study of normal donors receiving G-CSF at 10 µg/kg/day showed that CD34$^+$ cell yield was threefold higher when apheresis was started at day 5 versus day 6 [45]. Another study reported that the peak time for cell mobilization was approximately 10 hours following G-CSF injection [62].

Chemokine receptor 4 (CXCR4) and stromal cell-derived factor 1-alpha (SDF-1α) are a receptor/ligand couplet that is important in the normal adhesion and release of CD34 cells from the marrow compartment [30,31]. Both of these molecules are degraded by proteases released from neutrophil degradation, thus contributing to CD34 mobilization following the neutrophilia observed after administration of G-CSF [19,20]. It has been noted that inhibition of this binding occurs in the presence of plerixafor (previously known as AMD3100), a reversible bycyclam inhibitor of the binding between these molecules. Injection of plerixafor in doses between 80–240 µg/kg SC was associated with only mild abdominal bloating, injection site erythema, and perioral paresthesias. Optimal doses, when given alone to myeloma patients, NHL patients, and normal volunteers, was 240 μg/kg SC [28,63].

Plerixafor was shown to be a modest mobilizing agent when given alone to patients with myeloma and NHL [63]. When given either alone or after 4 days of G-CSF, optimal mobilization (two- to threefold above the level of CD34$^+$ cells/mL induced by G-CSF alone) occurred approximately 6–9 hours after the dose of plerixafor [63–65]. The combined use of plerixafor (240 μg/kg SC the night before each apheresis) plus G-CSF (10 μg/kg/day SC × 4 days) was significantly more effective than G-CSF or plerixafor alone for the mobilization of HSCs in patients with myeloma and NHL [65]. Data from the 25 patients in this phase II study demonstrated that none of the patients initially given plerixafor + G-CSF failed to reach the minimum target of >2 × 10^6 CD34/kg after four apheresis collections. In contrast, 9/25 patients failed to reach this target when initially given G-CSF alone. All nine of the patients that failed to mobilize with G-CSF alone were successfully remobilized with G-CSF and plerixafor. After mobilization with plerixafor plus G-CSF, 56% of the patients reached the minimum CD34 cell dose after one apheresis and all patients reached the minimum target after 2 days of apheresis. Mobilization with G-CSF alone resulted in only 36% of the patients reaching this minimum target after 2 days of apheresis. Thus, plerixafor appears to be an active mobilizing agent in humans especially when combined with G-CSF. These data have provided the foundation for two large randomized trials in which myeloma and NHL patients were mobilized with either G-CSF (10 μg/kg/day) or G-CSF plus plerixafor (240 μg/kg/day given the evening before each apheresis) in preparation for ASCT [66,67]. The primary endpoint of the myeloma study was acquisition of 6 × 10^6 CD34/kg (sufficient for tandem autologous hematopoietic stem cell transplants). A total of 106 of 148 (71.6%) patients in the plerixafor group and 53 of 154 (34.4%) patients in the placebo group met the primary endpoint ($p < 0.001$). A total of 54% of plerixafor-treated patients reached target after one apheresis, whereas 56% of the placebo-treated patients required four apheresis procedures to reach target [66]. The primary endpoint of the NHL trial was >5 × 10^6 CD34/kg in four or fewer apheresis collections. In this second study by DiPersio and colleagues, the addition of plerixafor to G-CSF led to significantly more patients collecting >5 × 10^6 CD34 cells in ≤ 4 days than G-CSF alone (59% vs. 20%; $p < 0.001$). One hundred and thirty-five patients (90%) in the plerixafor group and 82 patients (55%) in the placebo group underwent transplantation after initial mobilization [67]. Median time to engraftment was similar in both groups. In both studies, plerixafor and G-CSF were well tolerated with the most common adverse events related to plerixafor being gastrointestinal disorders and injection site reactions [66,67].

Combination cytokine, pegylated cytokine, and cytokine plus chemotherapy-induced mobilization

Despite a phase I/II report of the value of combination cytokine therapy, most notably the sequence of GM-CSF followed by G-CSF, the additional time and expense of using two cytokines in this fashion and a negative phase III study have prevented widespread adoption of this approach [55,68]. Other cytokines that are capable of PBPC mobilization as a single agent include SCF, IL-12, and IL-3 [69–72] but their efficacy has been marginal and toxicity has precluded their general use or FDA approval for this purpose.

Recently, pegylated G-CSF has been developed and approved for use to augment neutrophil recovery following chemotherapy. This compound, pegfilgrastim, has also been used to mobilize CD34 cells when administered following chemotherapy and in most phase II trials appears roughly equivalent to daily doses of G-CSF [73–75].

Because IL-2 stimulates cellular immunity and T-cell progenitors, it has the potential to promote antitumor immunity within an autograft. These characteristics make IL-2 an attractive candidate for co-stimulation of immunologic effector cells in concert with other cytokines, such as G-CSF, that are more effective for progenitor cell mobilization. While IL-2 may enhance the number and function of antitumor effector cells, it unfortunately also impairs the mobilization of the CD34$^+$ cells [76], thereby limiting its application in the context of hematopoietic progenitor cell mobilization.

Studies have shown that patients mobilized with cyclophosphamide (CY) plus G-CSF resulted in increased numbers of mobilized PBPCs compared to either chemotherapy or G-CSF alone (Table 40.3) [77,78]. In a randomized trial comparing mobilization with G-CSF alone with CY plus G-CSF in patients with refractory lymphoma, the addition of CY resulted in a threefold increase in CD34$^+$ cell yield, but this did not translate into a shorter time to engraftment [77]. A randomized, cross-over trial compared CY plus G-CSF with GM-CSF plus G-CSF within the same patients. The CY-containing regimen resulted in a 2.7-fold increase in CD34$^+$ PBPCs over that resulting from the cytokines alone [78]. A small randomized study compared 5 μg/kg daily GCSF plus CY, 2 gm/m^2 with 10 μg/kg G-CSF and found no difference in regard to CD34 yield or count recovery post-transplant, but increased toxicity with the addition of CY [79]. Another randomized, phase III trial compared regimens of G-CSF, GM-CSF and sequential GM-CSF then G-CSF following myelosuppressive chemotherapy. Compared to patients receiving GM-CSF alone, patients receiving G-CSF alone yielded more CD34$^+$ cells/kg, had fewer aphereses and had a faster time to neutrophil recovery. There were no significant differences between groups receiving G-CSF alone and sequential GM-CSF followed by G-CSF [54]. These studies illustrate the improved potency of regimens containing both myelosuppressive chemotherapy and hematopoietic growth factors. At the same time, these increased PBPC yields have been accompanied by greater toxicity as a result of the concurrent administration of chemotherapy and a potential increase in the risk of myelodysplasia compared to the use of cytokines alone in some [79,80], but not all reports [81–84]. In the study by Wood, an intermediate dose of etoposide (750 mg/m^2), split over 2 days, plus G-CSF resulted in collection of >5 × 10^6 CD34 cells/kg in 1 or 2 days in 99% of 152 myeloma subjects studied, including 109 subjects who had received prior IMID therapy [83].

Table 40.3 Comparison of cytokine alone versus cytokine + chemotherapy

No. of patients	Comparison	Observation	Ref.
47	G-CSF alone vs. chemo + G-CSF	Chemo + G-CSF group: 2.9-fold increase in CD34+ cell yield	[77]
96	GM-CSF followed by G-CSF vs. chemo + G-CSF	Chemo + G-CSF: 2.7-fold increase in CD34+ cell yield yield compared to cytokine alone group	[78]
79	Randomized trial of G-CSF 10 μg/kg/d vs. cyclophosphamide 2 gm/m^2 + G-CSF 5 μg/kg/d	Equivalent CD34 yields and post-transplant count recovery days of hospitalization and fever were fewer with G-CSF alone with fewer	[79]

chemo, chemotherapy; di-CEP, cyclophosphamide, etoposide and cisplatin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor.

The optimal doses of G-CSF have been investigated in a number of studies. In a randomized controlled trial, patients received either 8 or 16 μg/kg/day G-CSF following standard mobilization chemotherapy. With the higher dose of G-CSF, the $CD34^+$ PBPC yield was significantly increased more than threefold and the time to neutrophil engraftment was significantly decreased [84]. A small dose escalation study by Lefrere compared G-CSF doses of 50, 75, 100, 125, and 10 $\mu g/m^2$ along with chemotherapy and found they achieved adequate CD34 collections in 84 of 96 of patients suggesting that lower doses of G-CSF may be sufficient for the great majority of patients [85]. Efforts have been made to determine an optimal CY mobilization dose as well. Intermediate dose CY, 4 g/m^2, has been used with G-CSF to collect PBPCs. Several studies have shown that a higher dose, 7 g/m^2, results in higher PBPC yield but also leads to increased toxicity without a significant reduction in time to engraftment and no overall improvement in engraftment or eventual disease outcome [86]. A retrospective study by Gertz indicated that while cyclophosphamide-induced mobilization led to a higher yield of CD34 cells/kg than did G-CSF alone, patients actually required a longer time to recover platelet counts of >50,000/μL, suggesting an impact of intermediate-dose CY (3 gm/m^2) on the marrow microenvironment [87]. In patients who failed mobilization with CY, high-dose cytarabine, or the combination of etoposide plus high-dose cyclophosphamide have been used with good results [88,89].

Optimal timing of G-CSF administration after mobilization chemotherapy is also uncertain. In one study, G-CSF doses ranging from 250 μg/day as a fixed dose up to 10 μg/kg/day were administered 4 or more days following completion of chemotherapy and led to adequate ($>2 \times 10^6$) or optimal ($>5 \times 10^6$) CD34 cells/kg in the majority of patients [90]. It also appears that among the various preparations of G-CSF that are available, there is no significant advantage for one preparation (filgrastim, lenograstim, or molgramostim) over another [73].

Because no single mobilization chemotherapy regimen is clearly superior to the others, another mobilization approach is to incorporate PBPC mobilization into a cycle of disease-specific chemotherapy. In patients with hematologic malignancies, regimens containing ifosfamide, carboplatin and etoposide (ICE), have been used successfully for concurrent tumor cytoreduction and mobilization chemotherapy [91]. Other standard regimens like DHAP [92], have also been used to mobilize and collect CD34 cells. It is also important to note that the addition of the anti-CD20 monoclonal antibody, rituximab, prior to CD34 mobilization and collection does not decrease CD34 yield [93,94] and may reduce contaminating tumor cells in the CD34 product.

Factors affecting yield of PBPC mobilization

It is important to note that most patients mobilize adequate numbers of $CD34^+$ cells using a regimen of G-CSF alone. Although the addition of chemotherapy improves $CD34^+$ yield, this comes at the expense of increased short-term toxicity and, possibly, the increased risk of secondary myelodysplastic syndrome [80]. Even with chemotherapy–growth factor combination regimens, it may be difficult to achieve an adequate $CD34^+$ cell yield in some patients. Most cancer patients undergoing mobilization therapy for PBPC harvest to support high-dose chemotherapy have been treated extensively with chemotherapeutic agents and may have malignancy involving their bone marrow. These factors impair the ability to mobilize PBPCs. Even in normal, previously untreated donors, mobilization with G-CSF results in a wide variability of $CD34^+$ cell doses with 5–15% of donors mobilizing a suboptimal yield of less than $2.5–5 \times 10^6$ $CD34^+$ cells/kg [95]. This variability makes predicting how well any one patient will mobilize quite difficult. However, several studies have identified predictors of poor PBPC yield. The amount of myelosuppressive therapy (both chemotherapy and radiation therapy) received prior to mobilization is the most important factor affecting $CD34^+$ yield [96,97]. In particular, stem cell toxic agents including nitrogen mustard, chlorambucil, procarbazine, melphalan, carmustine, and >7.5 g CY were strongly associated with poor mobilization as is the prolonged use of fludarabine, a purine analogue commonly used for treatment of follicular lymphoma and chronic lymphocytic leukemia [97,98]. The number of chemotherapeutic regimens and duration of exposure to chemotherapy (>12 months) [99] also predict poor mobilization, but shorter courses of alkylating agents do not necessarily preclude good CD34 cell mobilization [99,100]. The intensity of the most recent cytotoxic drug administration relative to mobilization and stem cell collection may also influence mobilization [101]. Finally, previous radiation, hypocellular marrow and refractory disease have been associated with poor mobilization [97]. Recent reports have also demonstrated that extensive prior lenalidomide (>4–6 cycles) can result in decreased mobilization capacity which may require the addition of chemotherapy or plerixafor as opposed to G-CSF alone to achieve a successful collection [19,49,81,83,84,102,103]. An especially important finding was recently reported by Ferraro and colleagues in which they described poor mobilization in a small cohort of patients who were diabetic and in mice made diabetic with streptozocin [104]. Given the prevalence of this disorder it will be critically important to assess the applicability of this finding to the large number of diabetic patients who would be candidates for high-dose therapy and autologous HCT.

Managing poorly mobilizing patients

Strategies to manage patients who do not mobilize well include the addition of harvested bone marrow, remobilization with a dose escalation of cytokines, or use of a more intensive or novel regimen (Table 40.4) [58,105–107]. In recent years, the inclusion of plerixafor either with G-CSF alone or in conjunction with G-CSF plus chemotherapy has significantly improved the yield of patients who had failed their initial mobilization [18–20,63–65,108–111]. One center has found that infusing a suboptimal PBPC product in combination with harvested bone marrow can achieve short- and long-term engraftment [106]. Others have used high-dose G-CSF at 16 and 32 μg/kg/day to successfully mobilize patients previously failing standard myelosuppressive chemotherapy plus G-CSF mobilization [107]. There will still be challenges for heavily treated patients and those for whom mobilization is unsuccessful even in

Table 40.4 Guidelines for the "hard to mobilize" patient [refs]

1. Add plerixafor at a dose of 0.24 mg/kg following G-CSF alone or G-CSF plus chemotherapy when circulating pre-apheresis CD34 count is low [63–67,108,109,111,115]
2. Increase chemotherapy dose: high-dose etoposide or 4–7 g/m^2 CY appears more effective than 2–4 g/m^2 but is more toxic [82,86,87]
3. Increase growth factor dose (up to 10–24 μg/kg G-CSF) and consider use of cytokine combinations such as G-CSF + GM-CSF [54,68]
4. Consider bone marrow harvest [106]
5. Prolong duration between last chemotherapy and planned collection
6. Use investigational agents such as defibrotide or BIO5192 [130,133]

BID, twice daily; CY, cyclophosphamide; G-CSF, granulocyte colony-stimulating factor; IL, interleukin.

the absence of identifiable risk factors, but the addition of plerixafor to initial therapy has significantly reduced the likelihood of poor mobilization [64–67,108].

While historical factors are often able to predict the likelihood of good or poor mobilization, an increasingly effective and widely used strategy is the monitoring of peripheral blood CD34 counts following either cytokine mobilization alone or following cytokines plus chemotherapy [47–49]. Whatever method is used to identify patients who are likely to provide a poor apheresis yield, there is no doubt that cost considerations are significant in regard to both the initial collection and subsequent efforts to re-mobilize patients [103,112]. In either case, it is increasingly common to include initiation of plerixafor if the circulating CD34 count is suboptimal on day 4 or 5 following initiation of G-CSF therapy (<10–20 CD34/μL of peripheral blood) or if the CD34 count is low following chemotherapy once the circulating blood counts reach a certain level [108,109,112–117]. Using an algorithm such as those proposed by Costa [113,114] or Attolica [115] allows the inclusion of plerixafor when it is needed ("just in time"), but not in those circumstances following either cytokine alone or cytokine plus chemotherapy-induced mobilization when the yield of CD34 cells is likely to be adequate without the addition of this new and effective, but costly agent.

Tumor contamination

Although PBPC products are less frequently contaminated with tumor cells than bone marrow, tumor cells have been detected in patients with lymphoma, multiple myeloma, and leukemia [118,119]. In a study that compared outcomes of patients with non-Hodgkin lymphoma receiving high-dose therapy followed by autologous transplantation, patients receiving tumor-free autografts had a significantly improved survival over those receiving minimally contaminated autografts, demonstrating the importance of decontaminating the PBPC product [118]. An important analysis of the IBMTR and EBMTR datasets was undertaken by Bierman [120] who reported that patients undergoing either purged or syngeneic donor transplants for non-Hodgkin lymphoma had a lower likelihood of relapse post-transplant than did patients undergoing unpurged transplants for this disease. While there was no improvement in overall survival in the purged group, this analysis nonetheless attests to the potential importance of tumor cell contamination in the infusion product as one cause for treatment failure following high-dose therapy for these patients. Several reports from the group in Milan using in vivo purging with rituximab for mantle cell lymphoma patients indicated that tumor cell polymerase chain reaction testing negative products could be obtained in the majority of patients and that this was associated with a durable remission of more than 50% at 5 years [121,122]. This is felt to be the principal reason why reports from several centers have suggested that long-term transplant results are improved for patients who receive rituximab prior to their autologous transplant for B-cell lymphomas [93,121,122].

In multiple myeloma patients, both positively selected CD34$^+$ Thy-1$^+$Lin$^-$ progenitor cells and B-cell lineage depleted PBPCs have been transplanted to support high-dose chemotherapy with elimination of detectable tumor contamination and good engraftment [119], but there has been no improvement in overall survival [123]. Although these techniques are promising, available results have not demonstrated a clear benefit as PBPCs are depleted in the selection process and overall survival has not been improved. These results suggest that while infused tumor cells may contribute to relapse following high-dose therapy and autologous HCT, the evidence for relapse following autologous, syngeneic, and allogeneic transplants all point to the need for more profound cytoreduction in patients as an equally if not more critical component of the development of curative strategies [120,122–124].

Future directions

Chemokines such as IL-8 and GRO-β induce both a rapid release of proteases (NE, CG, and MMP-9) and HSCs from the BM into the blood. This effect by IL-8, GRO-β and N-terminal truncated of GRO-β, SB-251353, currently in early clinical testing, occurs in 30 minutes to 9 hours in mouse and humans [24,25,125]. Other second-generation CXCR4 inhibitors are either in development or are in early stage clinical trials as both normal and leukemic stem cell mobilization-inducing agents [18–20].

While the majority of patients receiving conventional mobilization regimens do produce adequate PBPC products, a significant, and not always predictable, portion of the population does not. Patients at risk for poor mobilization yields represent a challenging clinical scenario requiring improved mobilization strategies. Higher cytokine and marrow suppressive chemotherapy doses can produce improved CD34$^+$ cell yields [55,77]; however, these higher yields do not always translate into a shorter time to engraftment. Cytokine combinations have also been used in heavily pretreated patients resulting in modestly increased CD34$^+$ PBPC yield [68]. Clearly, innovative approaches are needed to address these patients, excellent summaries of which are provided in the review of stem cell mobilization with agents other than G-CSF [18,19].

Novel methods of mobilizing PBPCs continue to be studied with a number of preclinical compounds under investigation (Table 40.5) [18,19,24,25,125–127]. Manipulation of the adhesive interactions between hematopoietic progenitor cells and the bone marrow stroma has much promise. Anti-integrin monoclonal antibodies have already been shown to increase circulating hematopoietic progenitor cells in non-human primates [127] and in mice [128]. Manipulation of the chemokine environment represents an exciting and potentially most readily available opportunity for improving mobilization. A truncated GRO-β chemokine agonist has been shown to induce a rapid mobilization of hematopoietic stem cells in mice and primates [24,25,125], as has IL-8 [18,19,25,129]. Preclinical and clinical investigations with compounds such as Flt3

Table 40.5 Preclinical mobilization studies

Preclinical compound	System	Observation	Ref.
GRO-β (SB-251353)	Mice/primates	Fivefold increase in CFU and CD34$^+$ cells relative to G-CSF alone and more primitive lineage negative cells than G-CSF alone	[24,125]
Flt3 ligand	Mice/primates	Marked increase in CFU or CD34$^+$ cells and synergy with G-CSF	[126,127]
Antibodies to LFA-1/Mac integrins	Mice	2.7-fold increase in cobblestone and CFU/mL	[128]
Small molecule inhibitor of VLA-4	Mice	30-fold increase which was additive with G-CSF and plerixafor	[133]
IL-8	Mice/primates	Increase in CFU/mL	[25,129]
IL-17	Mice	Increase in CFU/mL	[132]

CFU, colony-forming unit; G-CSF, granulocyte colony-stimulating factor; IL, interleukin.

Table 40.6 Recommendations for "standard" mobilization regimens

Regimen	Advantages	Disadvantages	Refs
G-CSF: 10–24μg/kg/day by QD or BID schedule	Adequate yield in most patients Low toxicity Reliable scheduling Low risk of MDS Appropriate for use in allogeneic patients	Lower yield than G-CSF + chemo	[45,47,53,54,56]
GM-CSF followed by G-CSF	Higher CD34+ cell yield than G-CSF alone Appropriate to consider for use in allogeneic patients	More expensive than G-CSF alone No proven benefit over G-CSF alone in allogeneic or autologous patients	[54,68]
Chemotherapy + G-CSF: CY 2–4g/m2 High-dose CY or VP16	Higher CD34+ cell yield than cytokine alone Enhanced cytoreduction pretransplant High CD34 yields	Greater toxicity Increased risk of MDS/AML post-transplant Uncertain scheduling; risk of MDS, mucositis, infection	[82,84,86,87]
Mid-dose VP-16	High CD34 yields and modest toxicity	10% risk of hospitalization	[83]
Standard chemotherapy regimen	Continued successful cytoreduction	Inappropriate for allogeneic patients	[91,92]
Add plerixafor following G-CSF or G-CSF + chemotherapy if CD34 count low on day of planned apheresis	Increased yield of CD34 cells and reduction in the frequency of aphereses required. More reliable scheduling than chemo + cytokine	Added expense if adequate yields obtained without the addition of plerixafor	[67–83,102,103,108, 110,111,113–117]

AML, acute myeloid leukemia; BID, twice daily; chemo, chemotherapy; CY, cyclophosphamide; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; MDS, myelodysplastic syndrome; VP16, etoposide.

ligand [126,127], defibrotide [130], human growth hormone [131], and IL-17 [132] and a small molecule inhibitor of VLA-4 [133], also hold promise but require additional study prior to clinical use. How best to integrate these newer cytokines and chemokines designed to manipulate the progenitor cell–bone marrow stroma interactions and whether these can provide a synergistic approach to PBPC mobilization remains to be determined. Finally, consensus groups such as the SIDEM and GITMO should be applauded in their efforts to provide useful guidelines for the practice of stem cell mobilization and apheresis as well as highlighting needed areas for research in the field [47].

Summary

The use of high-dose therapy and autologous PBPC-supported transplantation has become an essential component of contemporary therapy for hematologic malignancies. The majority of patients will undergo successful mobilization and collection of sufficient PBPC with standard approaches to permit safe and effective autologous transplant procedures (Table 40.6). Despite these advances in PBPC acquisition, a significant minority of patients will have inadequate yields of PBPC and will continue to be the focus of research efforts designed to understand better the mechanisms of PBPC mobilization and to identify improved methods for their collection and administration.
